A great variety of cultural reactions, not only the conventional sugar fermentations, formation of indol from tryptophan, etc., but various kinds of specialized tests, such

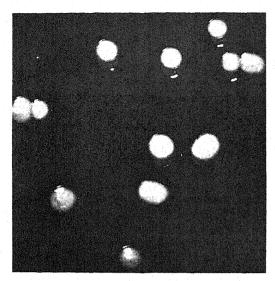

Figure 104. Colonies of Salmonella typhimurium (aertrycke) on nutrient agar, 24-hour culture. × 3.

as the utilization of the tartaric acids and malonate and the amino acid decarboxylase activity, have been useful in the physiological characterization of bacteria of this group.^{26, 28}

Toxins. Like the other enteric bacilli, the Salmonellas do not form exotoxins but all contain endotoxins. These are the polysaccharide-polypeptide-lipid complexes extractable from the intact cells with trichloracetic acid or glycols and are extracted as toxic lipopolysaccharide in 50 per cent

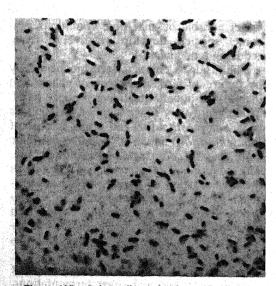

Figure 105. Salmonella typhi. Smear from a pure culture, Sommersby strain. Note the variation in size from coccoid to bacillary forms. Fuchsin; × 1050.

phenol. They appear to occur largely in the cell wall of the bacteria. These endotoxins, together with those of the coliform bacilli, have been taken as prototypes and most of the information available on endotoxins (Chap. Nine) has been derived from them.

The toxicity is nonspecific in the sense that endotoxins from whatever source produce substantially the same reactions on parenteral inoculation. The more obvious responses are fever and alteration in capillary permeability, the former probably contributing to the symptoms of the disease. The endotoxins are antigenic, stimulating the formation of agglutinating, precipitating, and protective antibody activity, but the antitoxic activity of antibody is of a low order. The specificity is that of the contained polysaccharide, and the endotoxins are apparently identical with the heat-stable somatic antigenic complex of the bacteria.⁵²

Another toxic substance, extractable in alcohol and named the Q substance, has been found in typhoid bacilli and other enteric bacilli, but its relation to the endotoxin is uncertain.

Immunological differentiation. As indicated above, the techniques of antigenic analysis have been developed in the study of the Salmonella group, and the antigenic composition of bacteria of this group is, perhaps, better known than that of any other bacteria. Many members of the group are immunologically complex; whether because they are innately so or because they are better known in this respect than most other bacteria is difficult to say.

Flagellar and somatic antigens. Two types of antigens are present in the bacteria of the Salmonella group, one associated with the cell substance and the other with the flagella. Noted by Smith and Reagh in 1903, the first was termed somatic antigen and the second flagellar antigen. These types were later observed by Weil and Felix, who designated them O and H antigens respectively. The O antigens are arbitrarily designated by numerals.

These two types of antigen, each of which may be, and frequently is, represented in a single bacterial strain by more than one component, differ from one another in several respects. The flagellar antigen is the more unstable and is destroyed by boiling and by exposure to alcohol or weak acid; somatic antigen, on the other hand, is stable to boiling, alcohol, and acid. Stock somatic

antigen for immunization purposes may be prepared by heating at 100° C., followed by treatment with alcohol and drying with acetone.21 Cultures on phenol agar (0.1 per cent) of bacteria normally containing both H and O antigens are found to contain only O antigens, the formation of flagellar antigen having been suppressed; H antigen reappears immediately on cultivation on nutrient agar. In the agglutination reaction, bacteria lacking flagellar antigen are characteristically clumped in a finely granular precipitate (O agglutination), while bacteria containing flagellar antigen are agglutinated in a coarse, flocculent precipitate (H agglutination).

The H and O agglutination titer of an antiserum may be determined by the use of H and O antigens in the agglutination test. H antigen is commonly prepared by adding an equal volume of formol (0.6 per cent formalin) saline to an 18- to 24-hour broth culture. In the preparation of somatic antigen the flagellar component is destroyed by treatment with alcohol; the growth from an 18- to 24-hour agar slant culture is emulsified in 1 to 2 ml. of absolute alcohol, heated at 60° C. for one hour, centrifuged, and the sediment suspended in 0.5 to 1 ml. saline. It may be used for slide agglutination or appropriately diluted for macroscopic agglutinin titrations.

These two types of antigen are immunologically independent, and the immunization of an animal with a microorganism containing both results in the production of antibodies to both. There is, however, a marked difference in titer, for the O antibody titer is generally much lower than that of the H antibody; in the writer's laboratory antiserums having H titers of 1:20,000 to 1:50,000 have shown O titers of 1:2000 or less.

SPECIFIC AND NONSPECIFIC FLAGELLAR ANTIGENS. The flagellar antigen is, in turn, of dual nature. One kind, designated as specific flagellar antigen, is individualistic and contributes in no small part to the immunological identity of a given Salmonella species. The other, termed nonspecific flagellar antigen, is made up of a limited number of components which are frequently shared by the various Salmonellas and hence contribute to the immunological relationship between the species of these bacteria. The specific flagellar antigens are arbitrarily designated by lower case letters (the choice

was unfortunate since the more recently discovered antigens are designated z_1 , z_2 , z_3 , etc.), and the nonspecific ones by Arabic numerals. Strains containing both kinds of H antigens are called diphasic, and those containing only either one or the other are called monophasic.

VI ANTIGENS. A somatic antigen, closely similar to, but not identical with, the O antigen complex, and designated Vi antigen, occurs in Sal. typhi, Sal. paratyphi A, Sal. paratyphi C, and Ballerup strains of paracolon bacilli.31 It resembles the O antigens in that it is present in the cell substance of the microorganisms and is extractable with trichloracetic acid but is more labile to heat in the presence of water and to treatment with dilute alkali.5, 48, 83 It is present in practically all strains of the typhoid bacillus on primary isolation, but in only some strains of para A and para C, and has the same immunological specificity in all the microorganisms in which it occurs. It was named Vi antigen, or "virulence antigen," because its presence is believed by some to be associated with virulence, and antibody to it is protective.34

Antigenic structure. The components of the somatic and flagellar antigenic mosaics of bacteria of this group have been worked out in detail by application of the methods of antigenic analysis, *i.e.*, reciprocal agglutinin absorption (Chap. Fourteen). Each of the serological types of Salmonella may be defined in immunological terms as antigenic formulas; representative antigenic formulas are shown in the accompanying table.

This kind of pattern is known as the Kauffmann-White schema.⁴⁶ There is some association between antigenic entities in that they tend to appear in recurring combinations, and there is evidence which suggests that certain of the immunologically separable activities, *i.e.*, by absorption of antibody, may be closely bound or even repre-

sent differing specificities contained in the same antigen molecule.14 Even with such associations to limit possible combinations of antigens within the same bacterium, a great number of serotypes is possible. New serotypes are continuously described, and from time to time the relevant data are aggregated.⁵⁸ Combinations of antigens, e.g., serotypes, can be produced in the laboratory (see below), and their natural occurrence is perhaps a consequence of conjugation and transduction as well as loss variations. In any case, the relative fluidity of antigenic structures leads to a certain skepticism as to the status of serotypes in classification (see below) although they are extremely useful in practice.72

Such antigenic structures have an illusory precision, illusory in that other antigenic components occur⁸⁴ but are neglected for practical purposes, and also because a single antigen, as designated by a symbol, may in fact be a complex in that there are small variations in it as it occurs in different microorganisms. Such differences, as well as similarities, are demonstrable in O antigen having polysaccharide specificities as chemical differences,⁵² and also in at least some of the flagellar antigens.⁶³

Salmonella typing. Partial or complete identification of such serotypes is carried out by the use of antiserums containing appropriate antibody; monospecific antiserums may be prepared by absorption to contain antibody to a single antigenic component when necessary. The serological identification of Salmonella strains in this way is known as Salmonella typing.

The somatic antigen provides the basis for primary separation of these serotypes into groups. There are 13 such groups in all, the first 12 made up of serotypes having common and identifying O antigens, and the last those serotypes which do not fit in elsewhere. These groups are:

I, II, XII
(I), IV , (X) , XII
VI, VII
VI, VIII
(I), IX , XII
III, X
III, X
III, XIX
XI
(I), XIII, XXIII
(I), VI, XIV, XXV
XVI

About 98 per cent of Salmonella strains isolated fall into the first eight groups, A to E₃ inclusive, and the identifying antigens of these groups are shown in boldface type above, while those antigens which occur in some but not all serotypes or strains of the group are shown in parentheses.

It is, then, a relatively simple matter to assign a strain to one or another of these groups by the use of appropriate antiserums, and identification may be carried considerably further with relatively few additional antiserums to the H antigens. The antigens used to prepare common typing antiserums are shown in the accompanying table. Complete analysis of the antigenic structure of a strain, or identification of the small portion of isolates falling outside these common somatic groups, becomes a specialized procedure.

Classification. The Salmonella group is relatively homogeneous in that these bacteria resemble one another more closely than they resemble other enteric bacilli, although the Arizona and Bethesda-Baller-up groups of paracolon bacilli are "Salmonella-like," and provide connecting links between Salmonella and the coliform bacilli. It is little more than a matter of arbitrary definition as to whether or not the Salmo-

nella group should be made larger and more complex by the inclusion within it of, for example, the Arizona group of paracolon bacilli.

Nomenclature within the group is another matter. Certain well-established differentiated by physiological methods prior to the application of antigenic analysis. such as those for which representative antigenic formulas are given, retain names such as Sal. typhi and Sal. enteritidis. As new and additional serotypes have been described, it has been customary to give them place names and implied species status, viz., Sal. newport, Sal. montevideo, Sal. panama. etc. An alternative to the use of a great many such names has been to give these but a single name, such as Sal. enterica, further identified by antigenic group or formula. This has not met with general acceptance, and the multiplicity of serotypes continue to be known by a multiplicity of names. As indicated earlier (Chap. Twenty), the use of such names is not to be taken as indicating that these serotypes are species in the Linnaean sense.

Variation. Possibly because the antigenic structure of the Salmonella group is known in considerable detail, three general types of variation may be differentiated. One of these is a type of fluctuating, completely reversible immunological variation known as phase variation, the second induced variation, and the last S-R dissociation known to occur in practically all bacteria.

Phase variation. The H antigens of certain Salmonella types can be separated into relatively stable components. This may be shown very simply by plating out such a type and carrying out slide agglutination of individual colonies with monospecific antiserum. About half the colonies will be found to contain one kind of antigen and about half the other. Apparently the individual bacterial cells do not contain both kinds of H antigen but are of two kinds in this This immunological character breeds true to only a limited extent, for if a colony is picked and subcultured in broth, platings of successive broth cultures will show a rapid reversion to the 50:50 ratio within a very few transfers. This is considered to be a mutation-back mutation process occurring at a relatively high (of the order of 10^{-3} to 10^{-4}) rate.^{49, 70} This type of immunological variation is called phase variation and the transitory immunological

types were originally called the specific phase, i.e., that characterized by the presence of specific flagellar antigens, and the nonspecific phase, i.e., that in which the nonspecific antigens occurred. Phase variation in one direction only, giving rise to a monophasic strain or mutant, has been observed.⁷³ This division is not as sharp as once thought, however, and now these phases are commonly referred to as phase 1 and phase 2 respectively. The Salmonella types that exist in two immunological phases are termed diphasic, while those that exist in only one phase, which may be either phase 1 or phase 2, are called monophasic. The presence of three phases appears to occur occasionally.50

Types of phase variation. Phase variation is somewhat more complex than this, however, and three types have been described. The first is the specific-nonspecific phase variation in which a specific antigen ordinarily occurring in phase 1 is linked with the nonspecific antigens of phase 2. The second is the so-called α - β phase variation in which an antigen occurring in phase 1 is linked with the antigens e, n, +, in phase 2. Five types of α - β phase variation have been reported. Lastly, there is a type of phase variation which has not been named in which the antigens of both phases are commonly found in phase 1.

O antigen variation. It is not clear whether this type of immunological variation occurs generally with respect to the somatic antigens. A similar variation, known as form variation, does occur, however. Of the three components of XII, designated XII₁, XII₂, and XII₃, XII₂ varies in that it is either strongly or weakly developed.^{24, 45} Antigen VI is likewise subdivided into VI₁ and VI₂ and form variation occurs in the former.²⁰

VW VARIATION. Variation in the Vi antigen content of the typhoid bacillus occurs as a tendency of freshly isolated, Vicontaining strains to lose Vi antigen within a few transplants on culture mediums. Vicontaining strains which presumably contain a maximum amount of this antigen are inagglutinable in O antiserum, the Vi antigen apparently having a masking effect, and are known as V strains. On culture, the V form becomes O-agglutinable, but still contains Vi antigen and absorbs Vi antibody from serum, and is called a VW strain. The VW form then loses its Vi antigen en-

tirely and becomes the W form. The Vi antigen is apparently independent of the other antigenic components of the typhoid bacillus, or those of other bacteria in which it occurs, and its presence or absence is unrelated to the nature of the O and H antigenic complexes.

It is to be emphasized that the immunological changes associated with phase variation are, so far as is known, normal, the bacterial strain seemingly existing in a sort of immunological equilibrium. These variations and the complete but temporary loss of flagellar antigen by cultivation on phenol agar noted above apparently bear no relation to the S-R dissociation, though, as indicated, they may be induced by a method which will induce dissociation, *i.e.*, cultivation in specific antiserum.

Induced variation. Antigenic changes may be produced in the H antigens of a number of Salmonella species by cultivation in the presence of appropriate antiserums. It has been shown that Sal. paratyphi A, a monophasic type stable in phase 1, can be induced to form phase 2 antigens by cultivation in antiserum specific to the phase 1 antigens. Conversely, diphasic types can be stabilized in one phase by cultivation in the presence of antiserum to the antigens of the other phase. By this means Salmonella "species" may be transformed, for example, Sal. simsbury into Sal. senftenberg.27 Furthermore, "new" species may be created from monophasic types by suppression of flagellar antigen through cultivation in the presence of monospecific antiserum, with the appearance of a hitherto unknown flagellar phase. A number of such induced antigens have subsequently been found to occur naturally.18

O antigen specificity is altered in the S-R dissociation as indicated below, but this is presumably unrelated to changes analogous to induced changes in H antigen that have been produced by cultivation in the presence of antiserum in semisolid mediums. By this means changes have been induced in O antigen within groups only; Sal. anatum has been changed to Sal. newington, and the change reversed.

Dissociation. S-R dissociation, similar in all respects to that known in other bacteria, occurs in cultures of these bacilli. The dissociation from smooth to rough is manifested as an alteration in colonial morphology and loss of virulence. The change

is reflected immunologically as a loss of specificity of the somatic antigens; *i.e.*, the rough forms remain motile. The specificity of these antigens is apparently determined by a polysaccharide haptene, and with the disappearance of the haptene the bacteria acquire a new and common immunological character in the somatic antigens, while the flagellar antigens remain unchanged. A mucoid or M phase in colonial morphology has been reported by some workers which is said to be associated with the development of a new immunological specificity.

Phage typing.³² Salmonella strains of the same serotype, and indistinguishable by serological, protective, or biochemical tests, may be subdivided into phage types on the basis of their susceptibility to lysis by different races of bacteriophage. Such differentiation is extremely useful for epidemiological purposes when the primary source of infection is the human carrier.

Phage typing of Vi-containing strains of $Sal.\ typhi$ is applied on an international scale, and $Sal.\ paratyphi\ A$ and $Sal.\ paratyphi\ B$ are also typed but to a lesser extent. The phage types of the typhoid bacillus are arbitrarily designated as type A, B, etc., with some subtypes, to type T, and there are nine additional types which are numbered or designated with a name, to give a total of 33 such types. Type E_1 is the most common all over the world, with type A a close second. In this country the commonest is type E_1 , followed in frequency by type C, type A, and type F_1 in that order, but about 10 per cent of strains cannot be typed.

The predominance of one or another of the phage types of Sal. typhi may characterize a geographical region. In the Western Hemisphere, types C, E₁, D₁, and A occur in that order in Canada, and types A, T, and E₁ in Venezuela. In England the most frequently occurring types are E₁, A, C, and D₁; in Denmark A, F₁, E₁, and C; in Portugal B₃, A, E₁, T, and D; etc. Other phage types are discontinuously distributed; viz., type M is found in Asia, in fact is commonest in Vietnam, and otherwise is found in Iran, France, and Poland.

There are four phage types of Sal. paratyphi A and 10 types of Sal. paratyphi B^{57, 62, 66} in both series designated by numbers. These have been less extensively studied than the phage types of Sal. typhi, and in both groups type 1 appears to be the commonest wherever studies have been

ECOLOGY 501

made. Other Salmonella serotypes have not been studied in any detail with respect to phage types, except *Sal. typhimurium*^{12, 33} of which some 80 phage types are distinguishable.

Ecology. 56, 60 As noted earlier, bacteria of the Salmonella group all appear to be obligate parasites, and they are not found apart from animal hosts. Sal. typhi, Sal. paratyphi A, and usually but not invariably Sal. paratyphi B are restricted to man. where they cause disease or persist in the carrier state. The remainder of this large group are parasites of lower animals, especially rodents and birds, although they are found occasionally in reptiles. The natural host of Sal. enteritidis, for example, seems to be the rat, and that of Sal. typhimurium, the so-called mouse typhoid bacillus, the mouse. Fowl are commonly infected. including chickens, turkeys, and ducks, and may constitute the largest reservoir of human infection; of other domestic animals, the pig is most commonly infected, especially with varieties of Sal. cholerae-suis, which is not, however, the etiological agent of hog cholera, a virus disease. Of a series of 2520 isolates²³ exclusive of Sal. pullorum and Sal. gallinarum, the causative agents of bacillary white diarrhea of chicks, 1258 were isolated from fowls, 532 from man, 475 from swine, 90 from rodents, 88 from carnivores, 53 from horses, and 20 from ruminants. These proportions reflect the kind of specimens examined and hardly constitute a random sample.

The isolates from human sources in this series include 41 types of Salmonella; of those occurring most frequently, 132 were Sal. paratyphi B, 60 were Sal. typhimurium, 53 were Sal. newport, 37 were Sal. newington, 28 were Sal. cholerae-suis var. Kunzendorf, 27 were Sal. panama, and 24 were Sal. montevideo. These proportions are probably reasonably representative, but one type or another may predominate in man in a given locality for a time and then, unaccountably, shift. For a period of several years, for example, Sal. montevideo was found in the great majority of specimens examined at the University of Chicago Clinics.

The presence of Salmonella is frequently associated with disease, both in man and in lower animals, and epidemics of Salmonella infection may occur in flocks of

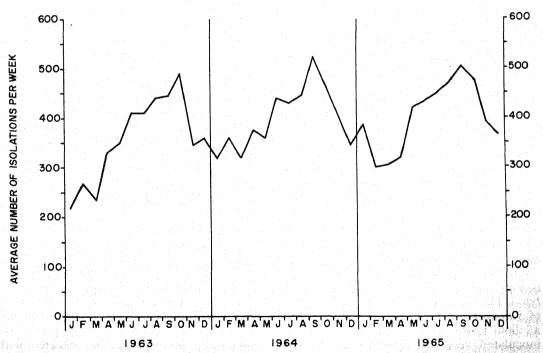

Figure 106. The incidence of Salmonella infection in man as indicated by the number of reported human isolations in the United States over the period 1963-1965. (Morbidity and Mortality Weekly Report, Annual Supplement, Vol. 14, No. 53. Communicable Disease Center, Public Health Service, U. S. Department of Health, Education, and Welfare.)

turkeys and similar situations. The infection may also be symptomless and the host act as a carrier, but the carrier state is usually not chronic except in the case of chronic human carriers of *Sal. typhi* where the gall-bladder or urinary bladder is infected, ap-

parently permanently.

Bacteriological diagnosis of Salmonella infection.25,42 The differentiation of the paratyphoid fevers from typhoid fever and the determination of the etiology of gastroenteritis caused by Salmonella is necessarily dependent on the isolation and identification of the causative microorganism. For isolation both enrichment culture and direct plating should be used; enrichment broth and differential selective agar plates should be inoculated simultaneously and, if the latter are negative, fresh plates can be inoculated from the enrichment culture. It is commonly observed that no single agar medium suffices, for with very few bacteria cultures may be isolated on one medium but not the others; at least two, and better three, kinds of differential agar should be used.

Two enrichment mediums are commonly used. Selenite-F broth contains 0.4 per cent sodium acid selenite, which is toxic for all gram-negative bacteria but is detoxified sufficiently in the presence of 1 per cent sodium phosphate to permit rapid growth of enteric pathogens while temporarily (eight to 12 hours) inhibiting E. coli.67 Tetrathionate broth contains thiosulfate, tetrathionate, and iodide, the tetrathionate being formed by oxidation of the thiosulfate with iodine. The differential selective agars used contain lactose and an indicator (often neutral red), together with bile or bile salts.38 Of these the most commonly used are desoxycholate-citrate agar (D-C), Shigella-Salmonella agar (S-S), and MacConkey agar. On these mediums the nonlactosefermenting bacteria form colorless opaque or translucent colonies which are readily differentiated from the red colonies of the lactose-fermenters.

The Wilson-Blair bismuth-sulfite medium is especially useful for the isolation of Sal. typhi. The colonies appear black, as do those of Sal. paratyphi B and Sal. enteritidis. The medium is strongly inhibitory and must be inoculated very heavily; consequently the colonies may not be pure cultures.

Typical colonies are picked and subcul-

tured in Kligler's iron agar or triple sugar iron agar; these mediums indicate acid or acid and gas formation from the sugars present and also the formation of hydrogen sulfide. After 24 hours' incubation, the growth is subcultured in urea medium, citrate medium, motility medium, gelatin, and lactose, sucrose, and mannitol broths. Lactose broth cultures should be retained for not less than two weeks to eliminate slow lactose fermentation. A positive lactose (and/or sucrose) fermentation, hydrolysis of urea, or indol formation eliminates Salmonella.

Further identification is serological.²² first with polyvalent antiserum which does not, however, eliminate certain of the dysentery bacilli (Flexner types 1 and 2) or serologically related paracolon bacilli of the Arizona group. Serological identification is made more precise by typing with monospecific serums as indicated earlier, either approximately or in detail. The usual technique is a rapid slide agglutination in which a drop of relatively heavy (milky) suspension of the bacteria is placed on a slide and mixed with a drop of antiserum, which may be appropriately diluted to eliminate crossreactions in some cases. Within a few minutes agglutination occurs, and the milky suspension appears to become curdled. This is most readily observed under low magnification, such as with a hand lens or a dissecting microscope. It is essential that a saline control be included, for rough forms agglutinate spontaneously in salt solution.

Pathogenicity for lower animals. Salmonella infection of rodents is quite common; Sal typhimurium and Sal. enteritidis cause infections of rats and mice, and these animals may become healthy carriers of the bacilli, a point of importance in connection with the epidemiology of food-poisoning outbreaks. Sal. typhimurium infection is by far the most common in the United States, and Sal. enteritidis less so than generally supposed. Preparations of "rat virus" or "Ratin" consist of these bacteria and are supposed to initiate an epidemic of disease in the rat population and hence destroy it. Not all the rats are killed and many of the survivors become healthy carriers.

Contrary to what had been previously supposed, the dog may be infected with Salmonellas; as high as 15 per cent incidence has been observed. While it seems unlikely

that the dog is an important reservoir of human infection, it has been found to transmit infection to man.¹³

Salmonella infection of the horse is also quite common. Infectious abortion of mares is caused by a specific microorganism, Sal. abortus equi, which has not been found in other animals. Man is only rarely infected. Sal. typhimurium has also occasionally been reported in horses. Abortion in sheep has been attributed to a member of the Salmonella group, Sal. abortus ovis. Salmonella is occasionally observed in a variety of other animals.

Birds are quite commonly infected with members of the Salmonella group. Epidemics due to Sal. typhimurium sometimes cause great destruction among canaries and other songbirds. Salmonella infections in turkeys occur and may be of such magnitude as to assume both economic and public health importance.1 Two barnyard diseases of great economic importance are due to specific Salmonella types: the bacillary white diarrhea of chicks caused by Sal. pullorum and fowl typhoid caused by Sal. gallinarum. Sal. pullorum may survive in the ovaries of fowls that recover from infection; diseased chicks may develop from the infected ova and communicate the disease to initially healthy members of the flock. Rare cases of human infection with Sal. pullorum have been reported, and it has been associated with epidemic foodborne gastroenteritis in some instances.

The typhoid bacillus. The typhoid bacillus is, in contrast to most members of the Salmonella group, almost completely non-pathogenic for lower animals except the chimpanzee, in which a disease closely

resembling typhoid fever is produced by oral inoculation. ¹⁹ There have been a number of accidental laboratory infections in man and, with the advent of chloramphenicol as an effective chemotherapeutic agent, the disease has been reproduced in human volunteers. The infecting dose for man in the latter kind of experiment has been found to be 10⁶ to 10⁷ bacilli.

The lethal dose for the mouse by the intraperitoneal route is of the order of many millions of bacilli and approaches the toxicity of the killed bacteria. Virulence for the mouse may be greatly increased by suspension of the bacilli in 5 per cent mucin, and the LD₅₀ by the intraperitoneal route may be on the order of 103 bacteria. The disease produced is a fulminating bacteremia, usually resulting in death within 48 hours. This kind of experimental infection has had wide application in assay of the immunogenic potency of vaccines and study of the relative importance to immunity of the Vi antigen and various fractions of the O antigenic complex.

A fatal infection with relatively small numbers of bacilli may be produced in the mouse by intracerebral inoculation.⁴⁷ The infection disseminates in the central nervous system to produce an acute purulent meningoencephalitis with secondary edema and pyrocephalus. Guinea pigs may be infected by direct inoculation of the gallbladder, and some animals so infected may become chronic carriers.⁴¹ This kind of infection, first described by Bingel with dysentery bacilli, has been used as a criterion of pathogenicity for a number of the Enterobacteriaceae.⁶⁹

Salmonella Infections

Salmonella infection in man is almost always acquired by ingestion of the microorganisms, usually as contamination of food, milk, or water. Occasionally double infections occur, *i.e.*, simultaneous infections with more than one kind of Salmonella, ⁶⁵ but these are not common. Two kinds of disease occur, one an acute gastroenteritis characterized by vomiting and diarrhea in which a small portion of patients become septicemic, and the bacteria are

found in the blood in relatively large numbers. The other is the typhoidal or continued fever type of disease in which bacteremia occurs in the initial stage of disease, and the symptoms are more general in nature. Sal. typhi, Sal. paratyphi A, usually Sal. paratyphi B, occasionally Sal. paratyphi C and related forms, and exceptionally almost any other Salmonella serotype, are responsible for the continued fevers. Acute gastroenteritis, on the other hand, is seldom if

ever due to infection with Sal. typhi or Sal. paratyphi A, and a minor portion of cases of infection with Sal. paratyphi B are of this kind, but the great majority of cases of gastroenteritis of Salmonella etiology are due to infection with the multiplicity of other Salmonella serotypes, largely Sal. typhimurium, Sal. enteritidis, Sal. cholerae-suis, etc. While, then, no sharp distinction can be made between the etiological agents of these two kinds of diseases, there is a general association.

In addition to these main types of disease, a wide variety of diseases may occasionally be associated with Salmonella infection.9 These microorganisms all have a predilection for the bone marrow, and bone infections are not uncommon, together with other localized infections, infections of the central nervous system, etc. A carrier state, usually transitory except in the case of chronic carriers of Sal. typhi (see below), occurs in man with discharge of the microorganisms in the feces. Infection may be acquired from human carriers, and such carriers should not, for example, be food handlers, but probably most human infections are from lower animals, viz., contamination of food with rodent feces, contamination of bulk and dried eggs by infected fowl, etc.

SALMONELLA GASTROENTERITIS

Gastroenteritis of Salmonella etiology is characterized by a short incubation period, as little as 12 hours in some cases, acute vomiting and diarrhea with slight rise in temperature, and rapid recovery, usually within a few days. Occasionally this kind of disease develops into a more serious septicemic condition, and there is a greater tendency to do so when the infectious agent is Sal. cholerae-suis and related forms of the "para C group." It is most often acquired by ingestion of contaminated food, and is called Salmonella food poisoning, but is an infection rather than an intoxication as in staphylococcal food poisoning. Salmonella food poisoning seems to be relatively more common than staphylococcal food poisoning in England, and the reverse in this country, but it is not clear that there is a real difference. 16, 17 No doubt some, and possibly many, of the descriptions of indigenous

cholera and cholera nostra in earlier writings refer to this kind of disease.

The general behavior of Salmonella infection is illustrated in a study of 7779 strains of Salmonella isolated between 1937 and 1955.61 In this group, gastroenteritis occurred in 68 per cent of the cases and was appreciably more severe in infants and persons over 50, and a typhoidal or septicemic condition occurred in 8.8 per cent. The over-all case fatality rate was 4.1 per cent, with more than half the fatalities occurring in infections with Sal typhimurium and Sal. cholerae-suis; in the latter infection, which tended to be septicemic, the case fatality rate was 20.3 per cent. In Sal. enteritidis infections, the case fatality rate was 5.8 per cent for all ages, but 15 per cent in those over 50.

Salmonella typhimurium (Salmonella aertrycke, Bacterium aertrycke, Bacterium typhimurium). This bacterium, most commonly isolated in food poisoning outbreaks in the United States and in Great Britain, closely resembles Sal. paratyphi B in its cultural characteristics but can be distinguished by its ability to produce acid in tartrate medium. Before differential tests were satisfactorily worked out, Sal. paratyphi B and Sal. typhimurium were commonly confused and both termed "para B." Sal. typhimurium is commonly found in a variety of infections in laboratory and domestic animals and in birds, and the "B. pestis caviae" of some writers and Nocard's "B. psittacosis" are, in fact, Sal. typhimurium. Most of the laboratory stock cultures labeled "Danysz virus" or "bacillus of mouse typhoid" are of the typhimurium type, but some are Sal. enteritidis.

Salmonella enteritidis (Bacterium enteritidis). Although found frequently in food-poisoning outbreaks, this bacterium is less common than Sal. typhimurium. It closely resembles Sal. typhimurium culturally but is said by some to differ in that it does not ferment inositol while typhimurium does. The inositol fermentation is, however, frequently not clear-cut; a lowering of pH may be noted but sometimes not to a sufficient degree to warrant calling the fermentation positive.

Salmonella cholerae-suis (Bacterium suipestifer, Bacterium cholerae-suis, the hog cholera bacillus, American suipestifer). This Salmonella is a member of a group of closely related bacteria, called the suipestifer group, which also contains Sal. paratyphi C or Eastern type, as noted above: Sal. cholerae-suis var. Kunzendorf or European type; and the Glässer-Voldagsen type, which is comprised of two species, Sal. typhi-suis and Sal. typhi-suis var. Voldagsen. These species may be differentiated from one another by a combination of cultural and serological methods. Sal. cholerae-suis formerly predominated in the United States. but now the Kunzendorf variety is found more often. This species has been implicated in outbreaks of paratyphoid gastroenteritis. although to a much lesser extent than either Sal. typhimurium or Sal. enteritidis. Sal. typhi-suis appears to be an animal (pig) pathogen, but several cases of human infection with the Voldagsen variety have occurred in the United States. The case fatality rate in cholerae-suis infections is 20 to 25 per cent in contrast to 5 per cent or less in infections with other Salmonellas

Other Salmonella species are less commonly implicated in human infections. Sal. thompson and Sal. newport, both related to the suipestifer group immunologically, have been observed a few times and other species but once; in fact, a number of the new Salmonella species described in recent years have been isolated from food implicated in outbreaks of enteritis.

TYPHOID AND PARATYPHOID FEVERS

Salmonella infection resulting in the continued fever kind of disease is characteristically typhoid fever, caused by Sal. typhi. As indicated above, the infectious nature of typhoid fever was suspected by the middle of the last century, and the causative agent was among the earlier of the pathogenic bacteria to be described. Within a few years paratyphoid fever was differentiated. Achard and Bensaude isolated a microorganism similar to, but not identical with, the typhoid bacillus from typhoid-like disease in 1896, and two years later Gwyn isolated a microorganism closely resembling Sal. enteritidis under similar circumstances. Since that time a number of investigators in different parts of the world have isolated similar bacteria from the blood of patients suffering from a disease that, so far as clinical symptoms are concerned, is substantially identical with typhoid fever.

Paratyphoid fever. Many cases of paratyphoid infection show a tendency to run a relatively mild course and are marked by a sudden onset with chills, but are otherwise very similar to infections with the typhoid bacillus. A certain proportion of the negative agglutination tests in apparent typhoid fever are probably a result of paratyphoid infection. The only method by which typhoid and paratyphoid fever can be distinguished is isolation and identification of the causal microorganism.

Many scattered cases of paratyphoid fever have been observed, and a number of more or less extensive epidemics have been reported as due to milk and other foods, to contact with human carriers, to sewage-polluted water and similar factors. Infection is probably most often acquired from carriers; the bacilli may be excreted for some weeks by convalescents, and subclinical undiagnosed cases are similarly a source of infection.³⁷ In general, the mode of dissemination of paratyphoid fever is practically identical with that of typhoid fever.

The frequency of the paratyphoid fevers as compared with typhoid fever varies a good deal in different localities, but most hospital records give a ratio of less than 1:10. In some regions the proportion of paratyphoid to typhoid may be as high as 1:4 or even more. During the First World War the proportion of paratyphoid to typhoid reached a high point. In the British armies in France during the years 1915 to 1918, the diagnosed paratyphoid fevers outnumbered the typhoid cases 2:1. In civilian populations in most countries paratyphoid fevers probably amount to 5 or 10 up to 50 per cent or more of all fully diagnosed enteric cases. Very young individuals appear to be the most susceptible to Salmonella infection, and an unduly large portion, perhaps 20 per cent, of cultures are from young children.

Salmonella paratyphi A (Bacillus paratyphosus A, Bacterium paratyphosum A, Salmonella paratyphi). This bacterium differs culturally from most of the other Salmonella species in its inability to ferment xylose, and it is, in addition, serologically distinct. Some outbreaks due to this microorganism have been traced to sewage-contaminated water supplies, others to food contaminated through the agency of human carriers. Paratyphoid fever due to Sal. paratyphi A is often very mild, 300 cases occur-

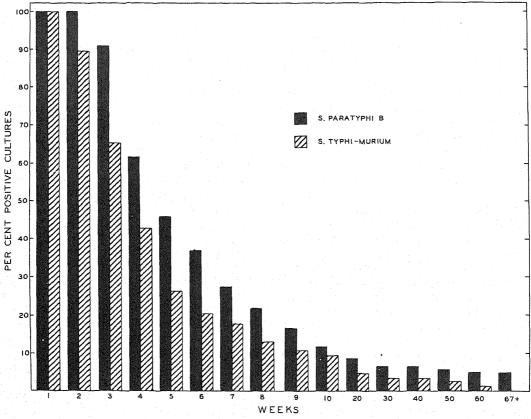

Figure 107. The persistence of Salmonella infection as indicated by positive fecal cultures by weeks after onset. (Data on 203 cases of Salmonella paratyphi B infection and 239 cases of Salmonella typhimurium infection, by Rubenstein, Feemster, and Smith. 59)

ring in a United States infantry regiment without a single death.

Salmonella paratyphi B (Bacillus paratyphosus B, Bacterium paratyphosum B, Salmonella schottmülleri). Sal. paratyphi B is readily differentiated from Sal. paratyphi A, but has confusing cultural and serological relations with certain Salmonella strains of the food poisoning types. As in the preceding species, the sources and modes of transmission are similar to those of typhoid fever. The source of the bacteria is generally the human carrier, but it has been reported that dogs have been found responsible for small epidemics, and in another instance a cow was responsible for cases of the disease. In the northern United States and in northern Europe infection with this species seems considerably more frequent than with Sal. paratyphi A.

Salmonella paratyphi C (Sal. hirschfeldii). Sal. paratyphi C has been found in enteric fevers in parts of Asia, Africa, and southeastern Europe and has been reported as an important cause of illness and death in British Guiana. Cases of endocarditis have been found to be caused by this and other suipestifer species. Although the type of disease is similar to the other enteric or intestinal forms, little is known about its epidemiology. This species is closely related biologically to the hog cholera or cholerae-suis strains described above.

Other species have been occasionally found: Sal. barielly, isolated from cases of mild pyrexia in India; Sal. enteritidis var. moscow, isolated from cases of paratyphoid fever in Russia and described by Russian bacteriologists as "Paratyphus N2"; Sal. sendai, isolated from cases of paratyphoid fever in Japan; and Sal. eastbourne, from a paratyphoid case in Eastbourne, England. In this country Sal. typhimurium, Sal. saint paul, Sal. oranienburg, Sal. hartford, Sal. sendai, Sal. panama, and others have been found associated with enteric fevers.

Typhoid fever.⁴³ Typhoid fever was for long one of the most widespread and im-

portant of all bacterial diseases. In the United States in 1900 there were 35,379 reported deaths from this disease, undoubtedly a low figure, and probably some 350,000 cases of typhoid fever in a population of 76.000.000 — in the course of a decade perhaps one person in every 20 to 25 contracted the disease. The prevalence of typhoid fever has greatly diminished in recent years, and a large part of this decrease has taken place in the large cities. Typhoid still persists, however, and epidemics occur from time to time, particularly in the smaller towns and rural areas. Much the same situation prevails in other countries, such as Great Britain.

The common symptoms of typhoid fever include frontal headache, lack of appetite, nosebleed, the development of rose spots on the abdomen, muscular weakness, and diarrhea. Sometimes considered primarily an intestinal infection, the disease is, in fact, a general invasion of the body, particularly of the lymphatic system. The gastrointestinal tract is the portal of entry of the bacilli into the body; the lymphatic tissues in the intestinal wall are first invaded. and the bacilli spread through the lymphatic system. After considerable multiplication has occurred (incubation period), the bacilli overflow into the blood and bacteriolysis takes place; the endotoxins which are liberated as a result of the destruction of the

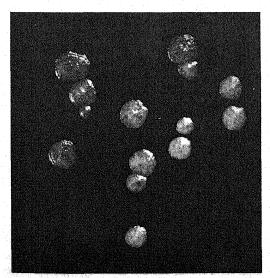

Figure 108. Colonies of typhoid bacillus on nutrient agar. Note the characteristic "maple leaf" irregular margin and slightly roughened glistening surface. × 6.

bacilli produce the symptoms of typhoid fever. Other evidence suggests that the body tissues may be invaded through the tonsils and gastric mucosa, but in any case the end result is the same, and typhoid fever is a general and not a localized infection.

The typhoid bacillus appears in the blood stream early in the disease, i.e., after the onset of symptoms, and may be cultured within the first 10 days in the majority of cases, either from a blood sample or from the clot of samples sent into a laboratory for agglutination tests.80,81 The presence of typhoid bacilli in the blood, however, does not constitute septicemia; in fact, probably little or no multiplication takes place. The bacilli are also present in the bone marrow early in the disease, and some have urged culture by sternal puncture to facilitate diagnosis. During and after the second week typhoid bacilli may be found with increasing frequency in the feces, and the proportion of positive blood cultures drops off. The bacilli are also excreted in the urine in perhaps 25 per cent of the cases. They may often be found early in the disease in the rose spots, not in the blood but in the lymphatic spaces.

On autopsy, the intestinal walls are usually found to be extensively ulcerated, Peyer's patches and the solitary glands of the intestine being particularly involved and containing typhoid bacilli. Perforation of the intestinal wall as a consequence of ulceration is a not uncommon occurrence. The spleen is enlarged and congested and usually contains large numbers of typhoid bacilli. In both the spleen and the liver the bacilli seen in stained sections occur in groups or masses rather sharply focalized; scattered individuals are not often found.

A variety of complications may occur. Laryngeal ulcer is occasionally observed. The gallbladder is often infected, and cystitis sometimes occurs. Suppurative and inflammatory processes may appear in other parts of the body. The osseous system seems especially open to attack, and affections of the periosteum, the bone marrow, and the joints have been traced to infection with Sal. typhi. Osteomyelitis may develop as long as six or seven years after recovery from typhoid fever, indicating that the typhoid bacillus can remain in contact with human tissues for years without losing its virulence. Other parts of the body are more rarely invaded during typhoid fever, but almost any

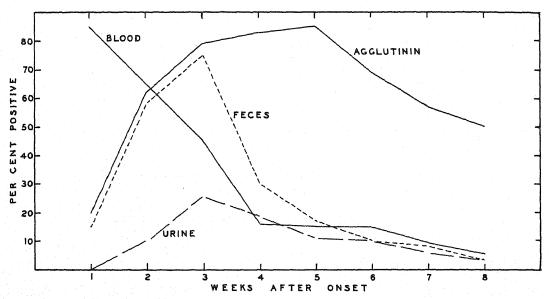

Figure 109. The approximate incidence of positive culture of blood, feces, and urine and the agglutinin response in typhoid fever.

organ can be attacked occasionally. The presence of *Sal. typhi* has been reported in a brain abscess, and the cerebral and meningeal symptoms occurring in many cases of typhoid fever are directly connected with the localization of the bacilli in the meninges; bacilli have been found in spinal fluid obtained by lumbar puncture. Pulmonary involvement may occur also, possibly more often than has been supposed.⁵⁵

Secondary or mixed infections, especially with the pyogenic cocci and the pneumococcus, are not at all uncommon and sometimes result in serious complications. Mixed infections with the tubercle bacillus and the anthrax bacillus have also been observed.

Chemotherapy. The typhoid bacillus is relatively resistant to penicillin in vitro, but although it is susceptible under these conditions to the other common antibiotics, chloramphenicol appears to be the only one that is reasonably effective in vivo. It is, therefore, the chemotherapeutic agent of choice and has given highly promising results. It has been reported that relapses tend to occur unless the drug is given for two to four weeks. Some attempts have been made to cure the carrier state by chemotherapy, with encouraging results in some instances but-not in others.⁷⁸

Carriers.⁵¹ About one-third of the individuals having typhoid fever discharge bacilli for a period of three weeks after the onset of illness and about 10 per cent for

eight to 10 weeks; these are known as convalescent carriers. A certain proportion continue to discharge typhoid bacilli for six months or more, and in many cases over a period of several years or throughout the whole of a long life.

The development of the carrier condition is probably dependent upon the invasion of the gallbladder in the case of the fecal carriers and of the urinary bladder in the case of the urinary carriers. Fecal carriers are more common than urinary carriers, and combined fecal and urinary carriers are relatively uncommon. The development of the urinary carrier state is apparently favored by pathology of the urinary tract produced, for example, by urinary schistosomiasis, and this probably accounts at least in part for the high incidence of urinary carriers in certain areas such as Egypt.39 Urinary carriers have been found to excrete antibody in the urine.4 It is not known why women are more commonly carriers than men. In the series studied by Ames and Robins,² 2.1 per cent of the males became chronic carriers as compared with 3.8 per cent of the females. Age is a factor also; according to the same workers the percentage of cases becoming carriers was 0.3 in the 0 to 9 and 10 to 19 age groups, but as high as 10.1 in the 50 to 59 age group. The usual estimates for all age groups vary from 0.5 to 11.6 per cent.

Typhoid bacilli need not be excreted con-

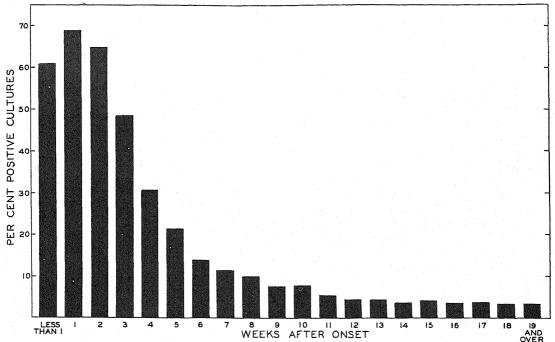

Figure 110. The persistence of typhoid bacillus infection as indicated by percentage of positive fecal cultures by weeks after onset. (Data from 374 cases in New York State, exclusive of New York City, by Ames and Robins.²)

tinuously; in fact, their intermittent appearance is very common, and weeks may elapse with negative cultures before the bacilli reappear. 10 The necessity for repeated examinations is obvious. The numbers of bacilli may vary widely, from 500,000 to 450,000,000 per gram of feces in one study.⁷⁴ A majority of carriers give the Widal reaction, and in most cases the opsonic index is abnormally high. Antibody to Vi antigen is found in the great majority of carriers but is only transitory if present at all in inoculated persons, and the use of the Vi agglutination test for the detection of carriers has given encouraging results64 but is not accepted as established.

Attempts to cure typhoid carriers by nonsurgical means, such as chemotherapy, vaccine therapy, or bacteriophage, have not been generally successful, and such procedures are not generally advocated at the present time. Removal of the gallbladder under suitable conditions is often effective in the case of fecal carriers; 70 per cent is the usually accepted figure. The chemotherapy of the carrier state is noted above.

The proportion of typhoid carriers in the general population is not known, owing to obvious practical and technical difficulties. It is probably quite different in different

localities and doubtless depends largely upon the prevalence of current and past typhoid infection. By a modified life table procedure Ames and Robins² estimated a carrier rate of 42 per 100,000 in New York State. On the basis of reported deaths and assuming a case fatality rate of 10 per cent and a chronic carrier incidence of 2 per cent in survivors, carrier rates have been estimated as 48 per 100,000 in Massachusetts and 288 per 100,000 in Mississippi.

The number of carriers throughout the United States is probably decreasing since they are no longer produced in such quantities as when typhoid fever was prevalent. By extrapolation Ames and Robins² calculated that the 2500 carriers in New York State in 1940 would be reduced to 200 by 1980.

Epidemiology. The typhoid bacillus is a strict parasite found only in man. Outside the human body multiplication, if it occurs at all, is insignificant, and for practical purposes may be neglected as a factor in the dissemination of the disease. As indicated above, the typhoid bacillus leaves the body in the feces or, less commonly, the urine, and enters the body of a new host via the alimentary tract. The epidemiology of typhoid fever, then, is predicated upon the

connection between the intestinal tract of the infected person and the mouth of the susceptible, and the factors that determine the spread of this disease are, essentially, those arising as a consequence of the interrelationships of the individuals or groups of individuals comprising the host population. The extent of the spread of typhoid is dependent upon the nature of the connecting links between individuals, and two epidemiological types of the disease may be distinguished, the one epidemic typhoid, the other endemic, or residual, typhoid.

Epidemic typhoid fever. Extensive outbreaks of typhoid fever necessarily involve a connecting link that is common to a great many people, and by far the most important vectors of this kind are water and milk. As pointed out elsewhere (Chap. Ten), waterborne typhoid fever, formerly all too common but by now relatively rare in the larger communities, occurs as a consequence of the contamination of a water supply with infectious fecal material, either as such or in the form of sewage. Waterborne epidemics of typhoid fever occur in the absence of chlorination, filtration, and other purification procedures and may be readily prevented. These epidemics tend to occur in the cold months of the year, particularly in the winter and early spring, and the incidence of the disease is unaffected by age, sex, or economic status. Such epidemics still occur occasionally, as in Zermatt in 1963.8

Milkborne typhoid fever, at the beginning of the twentieth century second only to waterborne typhoid in extent and importance, follows the route of the milkman and, as might be expected, tends to occur in the lower age groups and in families of higher economic status. The general use of pasteurization has practically eliminated milkborne typhoid fever.

Foodborne typhoid fever may take on epidemic proportions in certain instances. An epidemic due to infected corned beef, for example, occurred in Aberdeen, Scotland in 1964.⁷⁹ Oysters and other shellfish have come into bad repute in this respect, for a number of typhoid epidemics in Great Britain and the United States have been found to be due to the eating of oysters grown near sewer outfalls or placed to "fatten" in the polluted waters of estuaries or creeks. Water cress, lettuce, radishes, or any vegetables or fruits which are liable

to come in contact with contaminated water or are sprayed with human excrement may give rise to small-scale epidemic typhoid fever.

Endemic typhoid fever. Although epidemic typhoid fever is largely eliminated in a given community through adequate sanitary control of water and milk supplies and such food supplies as are susceptible to the application of effective control measures, the disease remains in an endemic form which is manifested as occasional cases or small groups of cases which appear from time to time. The seasonal incidence is quite different from that of waterborne typhoid; for some years there has been a sharp peak in the summer, but with continued reduction in the incidence of the disease, this has tended to disappear to give a relatively even distribution of cases throughout the year. The source of infection is, of course, the case, frank or ambulatory, or the healthy carrier. Instances of direct contact infection are unquestionably more common than is generally recognized, and the dissemination of typhoid bacilli from the infected individual to his immediate associates is undoubtedly responsible for the majority of cases of residual typhoid. Carriers are of particular importance in that they constitute semipermanent foci of infection and, when employed as food handlers, may be the cause of small epidemics. The most notorious instance of this kind was that of Mary Mallon, "Typhoid Mary," who was unknowingly the cause of some 26 cases of typhoid fever in seven different families. Under special circumstances, such as prevail among troops, contact infection may assume epidemic proportions.

The reduction in the prevalence of typhoid fever in the last few decades is attributable almost entirely to elimination of the great waterborne and milkborne epidemics. As noted above, epidemics still occur, and their control is a matter of putting into practice existing knowledge. Residual typhoid, however, is much more difficult to control; the detection and supervision of all carriers, or even the elimination of carriers as food handlers, is a practical impossibility. There is reason to believe that with continued control of epidemic typhoid fever. the reduction in the proportion of carriers may well be reflected in a reduced incidence of the disease in the epidemic form.

Immunity. An attack of typhoid fever

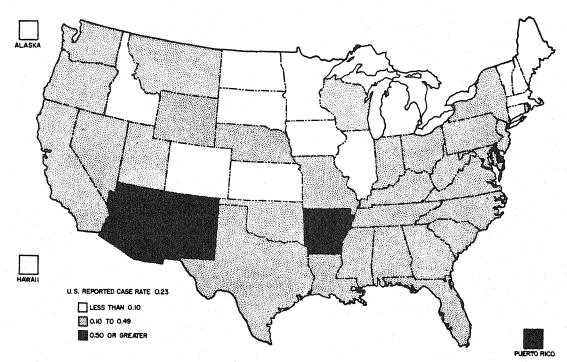

Figure 111. Geographical distribution of typhoid fever as cases per 100,000 in the United States in 1965. (Morbidity and Mortality Weekly Report, Annual Supplement, Vol. 14, No. 53. Communicable Disease Center, Public Health Service, U. S. Department of Health, Education, and Welfare.)

confers a certain degree of immunity, although instances of two or even more attacks in the same individual are not unknown.35 Animal experiment has shown that it is possible to obtain a high degree of immunity in rabbits and guinea pigs against intraperitoneal inoculation. Recovery from experimental enteric infection in the chimpanzee is also associated with an immunity to subsequent challenge by the oral route, 18 months after the primary infection.36 The immunity is associated with the development of humoral antibodies such as agglutinins, precipitins, and the like. Lysin is also produced, and, like the cholera vibrio, the typhoid bacillus undergoes visible dissolution and disintegration in the peritoneal cavity of the immune animal.

In man recovery from typhoid fever is also accompanied by the appearance of demonstrable antibodies. In most instances agglutinins appear during the course of the disease, sometimes as early as the fifth day (over 90 per cent by the fourth week), and their presence is the basis of the Widal test used for diagnostic purposes.

The Widal test.⁴⁴ In its original form the Widal test was a slide agglutination test, and agglutination of typhoid bacilli by pa-

tient's serum in a dilution of 1:50 or more was considered positive. The development of knowledge of the antigenic structure of the typhoid and paratyphoid bacilli in recent years has resulted in a somewhat better understanding of the value and limitations of the agglutination test in the diagnosis of typhoid fever. At the present time the test is a macroscopic one and is carried out with both H and O antigens. The interpretation of a single such test must take into consideration ancillary data such as a previous immunization or attack of typhoid fever and the prevalence of endemic typhoid in the general population. It is, therefore, difficult to set arbitrary limits; in most instances an O titer of 1:100 and an H titer of 1:200 may be regarded as significant. A point of some interest is the lack of sharp antigenic specificity of human serums as compared with the specificity of experimentally produced rabbit antiserums.

The interpretation of the Widal test in immunized persons is often difficult, since both H and O agglutinins are formed in response to the vaccine. Titers fall after immunization but may persist at moderate levels for many months. Furthermore, the agglutinin titer may rise in anamnestic response to a febrile

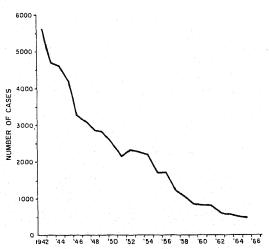

Figure 112. Cases of typhoid fever reported in the United States, 1942-1965. (Morbidity and Mortality Weekly Report, Annual Supplement, Vol. 14, No. 53. Communicable Disease Center, Public Health Service, U. S. Department of Health, Education, and Welfare.)

condition. The extent to which this occurs is not definitely known, and some data suggest that it is significant while others do not. Such an anamnestic reaction is particularly prone to occur in typhus fever, and typhoid agglutinin titers as high as 1:800 have been observed. There is some evidence that an "agglutinin curve," obtained by periodic agglutinin titrations, has diagnostic value in that it continues to rise in typhoid fever but usually does not do so in the anamnestic reaction.

Prophylactic inoculation. 6, 30 vaccine has been used for many years to produce an active prophylactic immunity. The efficacy of such immunization is indicated by the marked reduction in incidence of the disease by mass inoculation, which is particularly applicable in military services. At the time of the Spanish-American War in 1898, 4422 cases of typhoid fever and 248 deaths occurred in a division of 10,759 men. Typhoid immunization has been compulsory in the United States Army since 1911, and has resulted in the practical disappearance of the disease. 11 The immunity so produced may be broken down, and typhoid fever in immunized military personnel has been observed from time to time^{3, 71} but is rare.

The vaccine consists of a saline suspension of typhoid bacilli, usually 1000 million per milliliter, which are killed by heat, phenol, formaldehyde, etc. Triple vaccine con-

taining para A and para B bacilli in addition to typhoid bacilli (TAB vaccine) to the same total concentration but in a ratio of 2:1:1 has been commonly used, but the desirability of including the paratyphoid bacilli at the expense of half the typhoid antigen is questioned from time to time. For primary immunization, the vaccine is given as three doses, 0.5, 1.0, and 1.0 ml., at weekly intervals. A single inoculation, 1.0 ml. subcutaneously or 0.1 to 0.2 ml. intradermally, within two to three years, suffices for booster inoculation.

Questions of the assay of the immunogenic potency of typhoid vaccines, and their antigenic composition are raised perennially. There are discrepancies between the results of field trials, studies of the experimental disease, and immunogenic potency tests, and no final answers are as yet possible.

The most commonly used immunogenic potency test is the mouse protection test, either active or passive. In this country groups of 30 mice are immunized with 0.5 ml. of a 1:10 dilution of the vaccine intraperitoneally, and challenged, in groups of 10, two weeks later with 1000, 10,000, and $100,000 \text{ LD}_{50}$ in the mucin-potentiated infection. At least 50 per cent of the mice should be protected against not less than 10,000 LD_{50} . Intracerebral challenge has been studied but is not generally used. Passive protection tests, carried out in a similar way, may be used to assay protective antibody in human or other serums.

Virulence of typhoid bacilli for the chimpanzee is associated with Vi antigen, ¹⁹ non-Vi strains producing only very mild disease, ⁷⁶ and the results of mouse protection tests have also indicated the greater immunogenic potency of Vi-containing typhoid vaccine. On the basis of the mouse test ⁷⁵ and the chimpanzee infection, ⁷⁷ it is apparent that antibody to the O-Vi antigenic complex is protective, while antibody to the H antigens is not.

A series of field trials have been carried out in British Guiana, Poland, Yugoslavia, and the USSR under the auspices of WHO, in which heat-killed vaccines preserved with phenol, alcohol-treated vaccines, and acetone-killed vaccines were used. The USSR vaccines also included an adjuvant lipopoly-saccharide antigen. In general, the heat-killed vaccines, containing H-O antigen were superior to those containing only O antigen, an observation at variance with the

results of their mouse protection immunogenic potency assays.⁶⁸ The status of the mouse test thus becomes quite uncertain as a measure of immunogenic potency in man.

Passive immunization. The use of antityphoid serum for therapeutic purposes has been considered by a number of workers, but there is still no conclusive evidence as to its value. Whether or not "anti-endotoxic" serums or other typhoid antiserums confer a passive immunity to typhoid infection in man is likewise not established.

ALCALIGENES FAECALIS

Alcaligenes faecalis or Bacterium faecalis alcaligenes closely resembles the typhoid bacillus morphologically, culturally and even in its growth on Endo, Conradi-Drigalski, and malachite green differential mediums. It has been found in feces and in water. It differs from the typhoid bacillus in the possession of one or more polar, instead of many peritrichous, flagella, and in distinct alkali production in mannitol and litmus milk, and it fails to produce acid from dextrose and other carbohydrates. It has been suggested that *Bact. alcaligenes* is a form of Bact. fluorescens non-liquefaciens which has lost the function of pigmentation, and it does have affinities with certain of the plant pathogens and soil bacteria. Its systematic position has been examined critically by Conn who

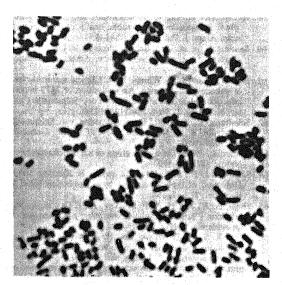

Figure 113. Alcaligenes faecalis. Smear from a pure culture. Fuchsin; × 2100.

has proposed a new genus, Agrobacterium, to include this bacillus together with Bact. radicicola and the bacterium of hairy root disease. Other species have been described as occurring in the intestinal tract, viz., A. metalcaligenes, A. bookeri, and A. recti, but these are not ordinarily differentiated from A. faecalis. Other varieties, A. viscosus and A. marshallii, are found in dairy products and produce a slimy alkalinity and ropiness in milk.

While A. faecalis is only feebly pathogenic, it has been found in cases of bacteremia, meningitis, infection of the gallbladder, renal tract, eye, lymph nodes, and appendix on occasion. Et has also been found to be the etiological agent of a disease closely resembling "red leg" (of Proteus etiology) in tree frogs. 53

Chapter Twenty-two

THE ENTERIC BACILLI

The Dysentery Bacilli

Dysentery is a clinical rather than an etiological entity, and its characteristic symptoms, diarrhea, abdominal pain, and blood in the stools, may occur either alone or as part of the syndrome of a number of diseases. In the former instance dysentery may be of protozoan or bacterial etiology. In addition there is evidence suggesting that a filterable agent, presumably a virus, can cause dysentery in man. A dysentery-like infection may be produced by some members of the Salmonella group, but usually another group of bacteria, the dysentery bacilli, is responsible.³

The dysentery bacilli are gram-negative, nonspore-forming rods related to the other enteric bacteria. Some of them resemble the anaerogenic type of coliform bacilli and the typhoid bacillus in that they ferment carbohydrates with the production of acid and no gas. Others are related to the other coliform bacilli and paracolon bacilli. None of the dysentery bacilli are motile, and hence they do not contain the two types of antigens found in the paratyphoid bacilli. As a group they differ from one another biochemically and immunologically. In general, their uncertain relationship to the other enteric bacilli, coupled with their own heterogeneity, has made their classification a difficult matter.

The dysentery bacilli are facultative anaerobes, and their optimum temperature for growth is 37° C. Their nutritive requirements are not complex in that they will grow upon the ordinary nutrient (beef extract) mediums. In synthetic solutions nicotinic acid is apparently required by some strains. They ferment glucose to much the same end products as the other enteric

forms—lactic acid together with smaller amounts of formic and acetic acids and ethyl alcohol. Like the other gram-negative bacilli, they are relatively resistant to the bacteriostatic action of dyes, and these substances may be incorporated in differential mediums for their isolation; eosin—methylene blue (EMB) agar is commonly used.

Classification. The dysentery are divided into two groups on the basis of the fermentation of mannitol, the nonmannitol fermenters including the Shiga bacillus. This distinction was of early importance and continues to be so in tropical regions and elsewhere where the Shiga bacillus occurs, for the dysentery produced by it is much more severe and has a higher case fatality rate than the other bacillary dysenteries, but is not of practical significance in this country, where there is little or no Shiga dysentery. In addition to the Shiga bacillus, this group also includes the so-called parashiga bacilli and the Schmitz bacillus. The group of mannitol fermenters is further subdivided on the basis of slow (four to seven days) fermentation of lactose and the fermentation of dulcitol and sorbitol.

In the past the nomenclature of the dysentery bacilli has been somewhat casual, and informal names such as the Shiga bacillus, the Flexner bacillus, the Strong bacillus, and the Hiss-Russell Y bacillus have had wide currency. The nomenclature has been further complicated, especially within the Flexner group, by various individual designations and by the vacillations of various formal systems of classification. The name Shigella for the genus has gained reasonably wide acceptance, and the dys-

entery bacilli are regarded as species of this single genus. Finally international agreement has been reached, based on species names and serotypes as suggested by Ewing,¹⁷ to introduce a welcome order and stability.

Four groups of dysentery bacilli, designated A, B, C, and D, each comprising a single species name with serotypes where appropriate, make up the genus Shigella. These are:

(1) The nonmannitol-fermenting bacilli:

Group A. Shigella dysenteriae. Including the Shiga dysentery bacillus, the Schmitz bacillus, and the Large-Sachs group of parashiga bacilli as immunologically independent serotypes.

(2) The mannitol-fermenting bacilli:

- (a) Group B. Shigella flexneri. The Flexner dysentery bacilli, having characteristic cultural reactions and antigens in common, i.e., group antigens, but differentiable into numbered serotypes.
- (b) Group C. Shigella boydii. Culturally similar to the Flexner bacilli, but serologically unrelated to them or to one another, differentiable as independent numbered serotypes and including the Newcastle-Manchester bacilli.
- (c) Group D. Shigella sonnei. The slow lactosefermenting dysentery bacilli, or Sonne-Duval bacilli, and including the bacilli formerly known as Sh. ceylonensis A.

These groups do not include various other bacilli found in association with diarrheal disease and described as dysentery bacilli, such as Sh. alkalescens and Sh. dispar, which are considered to be coliforms, or bacilli such as Sh. arabinotarda types A and B, which are identical with group A serotypes.

The nomenclature used by Russian workers differs from the foregoing, a matter of some practical importance, but Ewing and his colleagues¹⁶ have brought the Russian nomenclature into juxtaposition with

the International Schema.

SHIGELLA DYSENTERIAE (GROUP A)

The dysentery bacilli making up this group are set apart by their inability to ferment mannitol. Sh. dysenteriae is immunologically heterogeneous, made up of 10 sharply separable serotypes arbitarily designated by numbers. The serotypes appear to be unrelated antigenically except for unilateral cross-reactions between some

strains of types 2 and 6, and some strains of types 3 and 5. Two of the serotypes, 2 and 10, are serologically related to *Sh. boydii* type 1 (see below) through the sharing of two or more factors, and type 8 is divisible into subtypes, 8a and 8b.¹⁵

Shigella dysenteriae type 1 (Bacterium dysenteriae, Shigella dysenteriae, Shigella shigae). This was the first of the dysentery bacilli to be described. It was found by the Japanese bacteriologist Shiga to be the etiological agent of epidemic dysentery in Japan in 1898, and was found by Kruse in Germany two years later. It subsequently became known that this bacillus had been isolated 10 years earlier by Chantemesse and Widal, who found it in postmortem cultures of bowel contents and mesenteric lymph nodes, but it had become established as the Shiga bacillus or the Shiga-Kruse bacillus.

The Shiga bacillus differs from the other dysentery bacilli in its marked toxicity for man and experimental animals. Two kinds of toxin are formed: an endotoxin closely bound to the cell substance which is a polysaccharide-lipid-polypeptide complex⁵³ that appears to have considerable immunizing activity as assayed by mouse protection, and an exotoxin found in filtrates of broth cultures, protein in nature and thermolabile. The exotoxin (neurotoxin) has an effect upon the nervous system and produces paralysis,46 while the endotoxin appears to act chiefly upon the alimentary tract. The neurotoxin is a true exotoxin12 and resembles diphtheria toxin in a number of respects. It is produced most abundantly in aerated culture, and its formation is affected by the iron concentration of the medium; toxin formation is prevented by 0.01 M iron and appreciably inhibited by as little as 0.000001 M. It has been prepared in highly purified form by van Heyningen and Gladstone³⁹ and found to be similar to diphtheria toxin in potency and in possible mode of action. The relationship of this toxin to the pathogenesis of bacillary dysentery of Sh. shigae etiology is not at all clear. The exotoxin, but not the endotoxin, may be inactivated by formaldehyde and the toxoid used as an immunizing agent. It has not yet been possible to destroy the toxicity of this or other dysentery bacillus endotoxins and at the same time retain antigenicity.

Shiga bacillus infections have been observed most frequently in India, Japan,

^{*}According to Ewing and Trabulsi.19

China, and other parts of Asia; they appear to be relatively rare in the United States.

Shigella dysenteriae type 2 (Schmitz bacillus, Bacterium schmitzii, Shigella schmitzi, Shigella ambigua). This serotype was described by Schmitz in 1917 as a cause of dysentery in a Rumanian war prison camp. It does not ferment mannitol but differs in that it produces indol and ferments sorbitol and rhamnose. The species is immunologically homogeneous except that freshly isolated strains contain two antigens, one of which is lost on continued cultivation, and antiserums prepared from stock strains may not agglutinate fresh strains too well. There is some cross-reaction, perhaps to one-quarter titer, with the Shiga bacillus, but agglutinins are not reciprocally absorbed. The Schmitz bacillus is related serologically to E. coli O112. Sh. dysenteriae type 2 has been found in Europe, India, the Sudan, and elsewhere. In the United States it is not as common as some of the other dysentery bacilli but is encountered with some frequency and implicated in extensive institutional and other outbreaks of dysentery,6,47 and as an important cause of dysentery among chimpanzees in captivity.35

Other serotypes. Strains of dysentery bacilli culturally identical with Sh. dysenteriae type 1 but immunologically unrelated were found by Dudgeon and Urquhart in Macedonia in 1919 and designated by them Bact. parashigae (-) in contrast to the Schmitz bacillus, which they termed Bact. parashigae (+). These

bacilli have been observed from time to time in various parts of the world, including the United States, associated with diarrheal disease. They were studied in some detail by Large and by Sachs and are sometimes known as the Large-Sachs group or Sachs group of dysentery bacilli. Sachs distinguished eight immunological types, but three of these were paracolon bacilli, leaving five valid types in all. The Sachs types are Q771, Q1167, Q1030, Q454, and Q902; these are now designated Sh. dysenteriae types 3, 4, 5, 6, and 7.

Other nonmannitol-fermenting dysentery bacilli which differ immunologically from type 1 have been described. Of these the organism designated *Sh. arabinotarda* type A and Gober and Stacy strain 8524 has been found to be identical with Q771, and *Sh. arabinotrada* type B with Q1167. Still another, *Sh. wakefield*, is a paracolon bacillus.

SHIGELLA FLEXNERI (GROUP B)

Soon after Shiga's discovery, Flexner, working in the Philippines, discovered other dysentery bacilli which for a time were not clearly differentiated. Flexner's bacilli and those described by Strong and Musgrave in 1900 differed from Sh. dysenteriae both serologically and in the fermentation of mannitol. Attempts to subdivide the bacilli of the Flexner group by biochemical methods have not been successful; a wide variety

may be separated on the basis of the variable fermentation of sucrose, dulcitol, sorbitol, maltose, raffinose, arabinose, inositol, and salicin, and indol formation, but such varieties are not correlated with immunological type and have had little practical value.

Shigella flexneri (Bacterium paradysenteriae, Pseudodysentery bacillus, Shigella paradysenteriae, Flexner's bacillus, Hiss and Russell's Y bacillus, Strong's bacillus).

Sh. flexneri is made up of a group of immunological types that are distinct and yet related to one another. Five immunological types were distinguished by Andrewes and Inman on the basis of the distribution of four antigens, V, W, X, and Z, which are designated as types V, W, X, Y, and Z. Subsequently Boyd reported evidence of the presence of type-specific and group-specific antigens in these types and in additional related forms and suggested that numbered types be substituted for the Andrewes and Inman types.

Further study¹⁴ has fully substantiated this view, and the commonly accepted serological types of *Sh. flexneri* are shown in the accompanying table. The nomenclature of these has become confused, since different designations for the same type have been used by various authors in various countries. The common synonymous designations are shown in this table, and the types are indi-

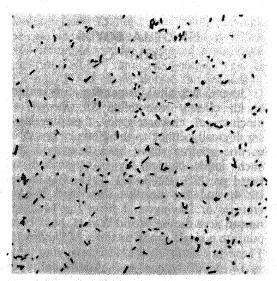

Figure 114. Shigella flexneri. Smear from a pure culture. Fuchsin; × 1050.

cated by Arabic numerals in accordance with the recommendation of the Shigella Commission to avoid confusion of Roman numerals with capital letters. As in the case of *Sh. dysenteriae*, the current Russian nomenclature differs from that of the International Schema; the correlations are shown in the accompanying table.

It may be noted here that certain nonmannitol-fermenting dysentery bacilli are closely related to the Sh. flexneri group on a serological basis and are, therefore, included in it. The Rio and Rabaul bacilli are Sh. flexneri type 4, but differ slightly in group antigens. The original Andrewes and Inman types are included in types 1, 2, and 3. Types 4 and 5 are the new types described by Boyd and originally called 103 and P119 respectively. Type 6, or Boyd 88, is not new but a variety of the Newcastle-Manchester bacillus that was first isolated from cases of dysentery in 1929. The X and Y types represent an as yet unsolved problem. These were so designated by Andrewes and Inman and apparently have no specific antigen; frequently cultures so labeled are found to be type 2, and in other instances specific agglutination may be masked by rough antigens.

Serological typing is readily carried out, and phage typing, useful with staphylococci and Salmonellas in particular, has not been of general interest. It has been reported³⁶ that preliminary investigation of phage sensitivities has indicated a close correlation with serological groups.

Colonial morphology, as accentuated by oblique transmitted light, appears to be associated with both virulence and antigenic content.⁹ Highly virulent colonial types contain a full complement of antigens, while morphologically distinct avirulent forms do not contain specific, or type, antigen, and are apparently transitional in the change from smooth to rough.

All of the Flexner bacilli are of world-wide distribution, the relative proportions varying from one locality to another. As a whole, Sh. flexneri is found in a large proportion of the dysentery cases in temperate climates, and even in tropical countries it is perhaps the most common of the dysentery bacilli. In this country, for example, 451 strains of a total of 769 isolated in routine examinations in Connecticut in 1940 to 1943 were Sh. flexneri, and of 1329 dysentery bacilli isolated from British and In-

dian troops in India, 999 were Flexner, 197 Shiga, 100 Schmitz, and 33 Sonne bacilli.

Sh. flexneri forms no soluble toxin or exotoxin but contains an endotoxin. It has been studied in some detail by Goebel and his co-workers.37 who have found that the somatic antigen which contains the toxicity is made up of a lipid component, a protein component, two carbohydrate components one of which contains labile acetyl groups, and a toxic component which Goebel believes to be a distinct substance and possibly associated with a purine or pyrimidine-like substance. In general, it has not been possible to detoxify the endotoxin without destroying its antigenicity. Mucinase is produced but to lower titer than by the cholera vibrio,25 but whether this activity contributes to the pathogenicity of these microorganisms is not clear.

SHIGELLA BOYDII

(GROUP C)

mannitol-fermenting dvsenterv bacilli closely resembling Sh. flexneri in biochemical characteristics, but unrelated serologically either to the Flexner group or to one another, have been described. Six such immunological types described by Boyd as 170, P288, D1, D19, P143, and P274, and the bacillus described as Sh. etousae or Lavington I from the Mediterranean area during World War II, have been put into a single group as types of Sh. boydii. These are listed in the accompanying table as Sh. boydii types 1 to 7. Additional types have been described. Some of these are related to coliform bacilli as well as to some of the other Boyd types; specifically types 10 and 11 are related to E. coli O105 and to Sh. boydii type 4.

The pathogenicity of these forms appears to be closely similar to that of *Sh. flexneri*, and their distribution seems to be ubiquitous. They have not, however, been studied in detail, as have, for example, the Flexner bacilli, with respect to chemical characterization of endotoxin and somatic antigens, effective immunity, etc.

Escherichia alkalescens. E. alkalescens was described by Andrewes in 1918. Unlike the other dysentery bacilli, these bacilli ferment dulcitol. For some time they have been regarded as of uncertain pathogenicity, but evidence is accumulating which indicates that they are associated with disease. They have been found associated with sporadic enteric disease, and small epidemics are reported. In the last few years E. alkalescens has been recognized more and more frequently in this country and appears to be more common than had been supposed. It is also pathogenic for experimental animals.

Strains of E. alkalescens have been regarded as biochemically distinct and immunologically homogeneous. Stuart et al.,58 however, have found that the species is made up of a graded series of biochemical types. They have also demonstrated the presence of five antigens, two major antigens designated A and B, and three minor antigens, C, D, and E, in these bacilli. A, B, and C are present in all typical strains, while D and E occur singly or in combination to give four subtypes. They are immunologically related to the colon bacilli through the paracolon group and to Boyd P274. Two immunologically unrelated types have been described⁵⁴ and designated type II and type III in distinction to the original or type I. It has been suggested that type II be Sh. tieté. Both of these types include strains which ferment lactose.

There has been some tendency to put *E. alkalescens* together with *E. dispar* (see below) to make an alkalescens-dispar group of enteric bacilli set apart from the other Shigellas as more closely related to the coliform bacilli.¹⁸

SHIGELLA SONNEI (GROUP D)

Lactose-fermenting dysentery bacilli discovered by Duval in 1904 have since

been rediscovered by quite a number of observers. By force of usage these bacteria have come to be known as the Sonne type and are designated Sh. sonnei (Sonne-Duval bacillus, Duval's bacillus, Sonne's group III). The Sonne bacillus ferments mannitol and does not produce indol; it is serologically distinctive and homogeneous. There are two immunological types of Sh. sonnei which are designated I and II. Type I contains one antigen in predominance, while type II contains both antigens in equal amounts. The difference in agglutination titers is of practical importance, and type II antiserum is the one of choice. The two antigens differ in biochemical properties; that of type I is extracted from the bacilli in 50 per cent glycerol, while that of type II is not extracted in glycerol but in 7 M. urea. The rough form appears to be a variant of type II, but whether a succession of type $I \rightarrow type IIs \rightarrow type IIr occurs is not al$ together clear.55 Type I tends to predominate in the acute disease and is mouse-virulent, while type II occurs for the most part in carriers and is not virulent for mice.5

The lactose fermentation is slow and may be delayed for a week or 10 days, and strains of this type were doubtless confused with Flexner bacilli by earlier workers. It is probably considerably more common in the United States than appears in the records. It has also been reported in warmer countries, and perhaps a more detailed study of the differentiation of the mannite-fermenting bacilli would increase the amount of dysentery properly ascribable to this microorganism. ⁵⁹

The slow lactose fermentation would appear to relate *Sh. sonnei* to members of the colon group and in particular the so-called paracolon bacilli, but their immunological homogeneity tends to set them off.

Escherichia dispar. Other lactose-fermenting dysentery bacilli were designated Bact. dispar by Andrewes. Some of Andrewes' strains were Sh. sonnei, but the type now termed dispar differs from the Sonne type in that sorbitol is fermented and indol is formed. E. dispar is serologically heterogeneous and not related to Sh. sonnei but appears to be related to certain Flexner strains. It has been found that a group of 37 strains could be separated into three immunological types, two related to one another and the third independent. E. dispar may be divided into two varieties, E. dispar var. ceylonensis which ferments dulcitol, and E. dispar var. madampensis which does not.

BACILLARY DYSENTERY

Bacillary dysentery is a relatively common disease of man, more so in the warmer climates, and tends to be associated with crowding under conditions favoring spread of the infection from the human reservoir. It is more prevalent in backward countries, especially in the tropics and subtropics. It is a perennial problem in military operations, less so than in the pre-bacteriological days when, for example, more men died of diarrheal disease during the Civil War in this country than were killed in battle. As a seriously incapacitating disease tending to occur in epidemic form, it continued to be a problem in World War I when, for instance, it was a significant element in the outcome of the battle of Gallipoli; during World War II especially in the South Pacific and Mediterranean areas; and subsequently in situations such as the landing of American troops in Lebanon in the late 1950's. While the proportion of Shiga bacillus infections has sharply declined to reduce mortality, bacillary dysentery remains an important incapacitating disease.

The infection remains a local one in the bowel with invasion of little more than the superficial tissues, and the debilitating effects are attributable largely to the loss of fluid and electrolyte consequent to the purging diarrhea. There is no doubt of the etiological relation of the dysentery bacilli to the disease; in addition to the presence of enormous numbers in the acute disease, the immune response as serum agglutinin, and the production of analogous disease in certain experimental animals (see below), accidental infections of man are well known and the disease has been produced in human volunteers. ^{56, 57}

Pathogenicity for man. 65 The incubation period of bacillary dysentery is generally short, about 48 hours, and the disease may be acute or tend to run a chronic course. Apart from the inflammatory, sometimes ulcerative or diphtheritic, lesions in the intestine (ulcerative colitis), the anatomical picture of dysentery presents little that is characteristic. The liver abscesses that are found, as a rule, in amebic dysentery are

absent in the bacterial diseases, one series having been reported of 1130 cases of bacillary dysentery without a single abscess. Dysentery bacilli are sometimes found in immense numbers in the dejecta, often in almost pure culture. They may be found at autopsy in the mesenteric glands, but, as a rule, not in the spleen or other internal organs, nor do they commonly occur in the blood or urine. The pathogenesis of the disease in experimental animals (see below) - an inital penetration of the epithelial cells and the development of foci of infection in the lamina propria-may closely simulate the disease process in man. Bacillary dysentery is, therefore, not a septicemia but an infection localized in the alimentary tract, in this respect resembling cholera rather than typhoid fever. Recurrent diarrheal disease may be caused by dysentery bacilli, indicating that the bacilli may persist in the bowel, possibly in the superficial layers of the intestinal epithelium, for long periods. 11, 21

In the large series of cases studied in Denmark caused by the Sonne and Flexner types, the case fatality was about 2 per cent. The Shiga bacillus dysentery of the tropics is much more often fatal (20 per cent). The clinical disease is considerably more severe in the Shiga infections than in Flexner infections, and complications, such as arthritis, are almost invariably associated with the former type of infection.

Some portion, apparently an increasing portion, of infant diarrhea is of dysentery bacillus etiology. Certain kinds of bacillary dysentery, especially Sh. sonnei infections, have become more common, and the epidemiology of the disease has changed so that the disease seems to be shifting from "the scourge of armies to the bane of nurseries,"59 where it may assume a fulminating, rapidly fatal form.44 Some investigators have isolated the dysentery bacilli from the excreta, particularly in those cases in which there is mucus in the stools. Those cases with which dysentery bacilli are associated do not appear to differ clinically from those in which they are not found, and it is uncertain just what proportion of cases of infant diarrhea is caused by the dysentery bacilli.

Carriers. It is probable that dysentery bacillus infection is very common, many of the infections going unrecognized because of the mildness of the symptoms. Persons with such infections are, of course, con-

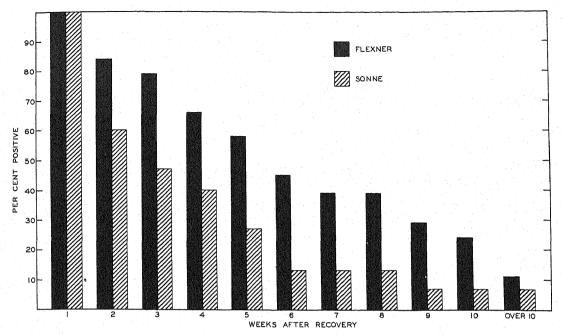

Figure 115. The persistence of dysentery bacilli in the feces of convalescents. (Prepared from data of Watt, Hardy, and DeCapito.⁶⁷)

valescent carriers who continue to discharge the bacilli for an average time of three to five weeks. It is not clear whether a permanent chronic carrier state analogous to the chronic typhoid bacillus carrier occurs, but many convalescents continue to discharge dysentery bacilli over long periods, and inapparent infection is not uncommon. In any case, it is the casual carrier and changing groups of casual carriers or ambulatory cases that are of primary importance in the maintenance and spread of the infection, and the disease persists in smoldering, endemic form. 40, 41

Pathogenicity for lower animals. The occurrence of bacillary dysentery in chimpanzees in captivity has been noted above, and other monkeys are commonly infected, usually with Sh. flexneri. It is probable that such infections are acquired from man and do not represent a natural infection in the wild state. The infection tends to be latent, with occasional appearance of symptoms, particularly when the animals are stressed.

A number of experimental infections have been described which vary in the degree to which they approximate the human disease. The fatal fulminating bacteremia produced in various experimental animals, such as the mouse, on intraperitoneal inocu-

lation is at best only distantly related to the human disease. An infection of the urinary bladder of the guinea pig may be produced by direct instillation of dysentery and certain other enteric bacilli,4 but it does not remain localized. The technique of inoculation of a ligated loop of the small bowel of the rabbit, devised by De and extensively used as an experimental model of cholera (Chap. Twenty-three), gives positive reactions, e.g., intraluminal fluid accumulation and bacterial multiplication, with dysentery bacilli considered to be virulent, but not with avirulent strains, e.g., Sonne II.1.61 A keratoconjunctivitis may be produced in the guinea pig eye by instillation of the bacilli, and this infection the histopathology closely resembles that found in experimental enteric infections. 50

Enteric infections, produced by oral administration of dysentery bacilli, have been studied in mice^{10, 51} and have been produced in the guinea pig with streptomycin-resistant bacilli administered in a streptomycin-containing inoculum and/or following pretreatment with the antibiotic,³⁴ or following parenteral inoculation of carbon tetrachloride.^{26, 27} Production of such infections also requires starvation and inhibition of peristalsis with laudanum or morphine. The experimental enteric infection most closely

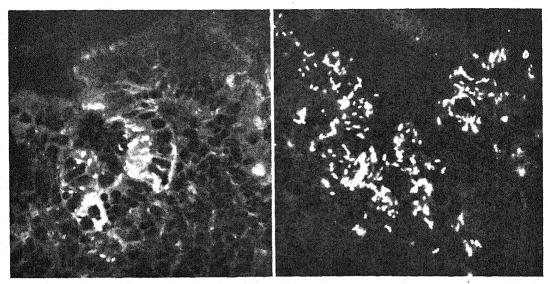

Figure 116. The pathogenesis of bacillary dysentery. Left, penetration of the ileal epithelium in the guinea pig at 12 hours by Sh. flexneri 2a; bacilli can be seen in the epithelial cells and some in the lamina propria. Right, small micro-ulcer in the colonic epithelium in the monkey 24 hours after infection; bacilli are present in the epithelial cells and in the lamina propria of the tubular glands of the colon. (LeBrec.) (Figure at right, courtesy of Journal of Bacteriology.)

simulating the human disease is that in the monkey, usually rhesus, which, as just indicated is also acquired naturally from man, and does not depend upon pretreatment to break down resistance.

Pathogenesis. Within the past few years the pathogenesis of bacillary dysentery and the nature of the virulence of dysentery bacilli have been clarified through the studies of Formal, LaBrec, and their co-workers. In essence, there are two stages in the former: penetration of the epithelial barrier by direct penetration of epithelial cells and into the lamina propria, and multiplication in the lamina propria as foci of infection. The subsequent breakdown of tissue with ulcer formation is due to endotoxin formed in situ rather than to the absorption of this, or other, toxin from the lumen of the bowel. Penetration of the epithelial barrier and the development of foci of infection in the deeper tissues has been demonstrated by the fluorescent antibody staining technique in the guinea pig48 and in the monkey.49 This occurs in the colon in the monkey, and in the guinea pig first in the small bowel as a consequence of opium-induced stasis and subsequently in the large bowel.28

In a series of elegant experiments resting on the genetic basis of virulence and genetic homology between dysentery bacilli and E. coli K-12, it was shown that penetration of epithelial cells and ability to multiply in the lamina propria are separable components of virulence. Avirulent variants were found to be unable to penetrate the epithelial barrier, remaining within the lumen of the bowel,²⁴ and full virulence could be restored to some variant strains by mating with *E. coli* K-12, supporting the assumption that the virulent phenotype is a polygenic phenomenon.²⁹ Conversely, hybrids of virulent Shigella and Escherichia are able to penetrate epithelial cells to give an inflammatory reaction in the lamina propria, but an abortive infection ensues since the hybrid does not multiply to produce a focus of infection.³⁰

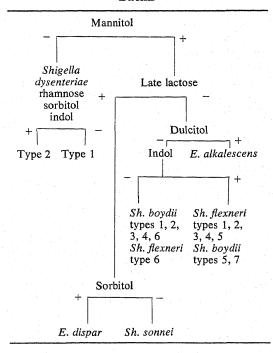

diagnosis.45 Since, **Bacteriological** indicated earlier, dysentery is a clinical rather than an etiological entity, the causative microorganism must be isolated and identified to allow a diagnosis of bacillary dysentery. The bacilli may be found in fecal specimens, and rectal swabs are cultured for the detection of carriers. The methods of enrichment culture and direct plating are essentially those used in the isolation of Salmonella and the typhoid bacillus. Desoxycholate-citrate and S-S agars are the most useful of the agar mediums; bismuthsulfite is not suitable because species other than Sh. flexneri are inhibited. Colonies are subcultured and identified by biochemical reactions and slide agglutination. For tentative serological identification polyvalent serums may be used, including (1) polyvalent Shiga serum, (2) polyvalent Flexner serum, (3) polyvalent Sh. boydii serum, (4) Sh. sonnei types I and II, (5) E. dispar types, and (6) E. alkalescens. The cross-reaction between these groups of antiserums may be removed by agglutinin absorption.13 For precise identification monospecific antiserums are required. The possibility of rapid presumptive diagnosis by identification of the four groups of Shigella in direct fecal smears stained with fluorescent antibody has been of considerable interest. It appears to be of value in Sonne infections, but false positive reactions tend to occur in Flexner infections.63

Chemotherapy. 46, 62 The sulfonamides are highly effective chemotherapeutic agents in bacillary dysentery and have been widely used, both for therapy and prophylaxis. The soluble compounds, such as sulfadiazine, are more effective than the nonabsorbable compounds. Streptomycin and the broadspectrum antibiotics, tetracycline and chloramphenicol, are also effective, as is furazolidone (Furoxone), and all of these also have been of interest as chemoprophylactic agents.

With the general use of sulfonamides, sulfonamide-resistant strains of dysentery bacilli became more and more common, resulting in increased usage of the other antimicrobial agents, with the consequence that multiple resistant strains were encountered more and more frequently. In 1960 it was found in Japan⁶⁴ that the multiple resistance (sulfonadmide-streptomycintetracycline-chloramphenicol) acquired by sensitive strains of Shigella, as well as other enteric bacilli, is episome-mediated and transferred in toto. The episome is designated the R-factor (Chap. Seven), and this kind of acquired drug resistance has been found to occur world-wide. Effective chemotherapy of bacillary dysentery, then, continues to offer practical difficulties.

Epidemiology. Infections caused by dysentery bacilli are probably far more common than is generally recognized. In 1945, 33,495 cases and 400 deaths were reported from 38 states, rates of 32.4 and 0.4 per 100,000 respectively. Attacks of severe illness grade off into mild and almost trivial attacks of simple diarrhea. Several outbreaks of typical "food poisoning" attributed to the Sonne bacillus are on record.

Biochemical Separation of the Dysentery Bacilli

In a number of localities where the careful bacteriological studies have been made, dysentery bacilli have been found widely distributed both in patients with gastrointestinal derangements and in the general population. Probably the most important single reservoir of infection is the human carrier, either convalescent or with inapparent infection. The extent to which the carrier state occurs has been appreciated only in recent years. In a study of dysentery bacillus infection in the normal population Watt and Hardy66 found Sh. flexneri in 11 per cent of the population in New Mexico, 4 per cent in Puerto Rico, 3 per cent in Georgia, and 0.1 per cent in New York City, with an estimated annual morbidity of 60 per cent in Puerto Rico, 48 per cent in New Mexico, and 20 per cent in Georgia, and an over-all ratio of convalescent or passive carriers to cases of 9:1.

Dysenteric infections seem to be most common in hot countries and in the summer months in temperate climates, although they may occur at any season of the year. The acute diarrheal disease occurring routinely in tropical countries, and known locally as "Gyppy tummy," "Delhi belly," etc., are frequently bacillary dysentery, the Flexner and Boyd types appearing to

be the most common where studies have been made.22,23 The spread of the disease is due to the more or less direct transfer of the specific bacillus from infected intestinal discharges to the alimentary tract of a fresh individual. Polluted water may play a part in some outbreaks but is apparently not nearly so important a factor in dysentery as it is in typhoid fever. Improper disposal of excreta permitting dissemination by flies, and the contamination of food by chronic carriers and convalescents, appear to be the most important factors in the spread of bacillary dysentery. The role of insects, especially flies, has been demonstrated,40 and is probably an important one, and the seasonal incidence of bacillary dysentery is in keeping with this. In the epidemic reported by Kuhns and Anderson infected flies were caught in kitchens and operating latrines; similar reports are not uncommon. The decline in diarrhea and enteritis and the shifting proportions of the etiologic agents of the last few decades are very likely a reflection of the general improvement in sanitary conditions. 60

At the present time in temperate climates dysentery flourishes especially in mental

hospitals and other large institutions, where lack of personal hygiene among the inmates favors the transfer of infection. Whenever it gains a foothold in these institutions it seems to be kept alive chiefly by chronic carriers and proves an obstinate problem. Weekly bacteriological examination in one institution showed that more than 50 per cent of the dysentery patients continued to excrete dysentery bacilli for long periods in one case over four and one-half years. Epidemic bacillary dysentery is also a disease of armies in the field, where opportunities for the dissemination of infection are frequently very great, and extensive outbreaks are common.

Although in small outbreaks a single type of dysentery bacillus may be found, in the larger outbreaks more than one type is almost always observed. The most common types in this country are the Flexner (often type 2a) and Sonne bacilli. The proportions differ from one area to another and with the season. In the fourth quarter of 1966, for example, the Flexner type occurred in 70 per cent and the Sonne type in 28 per cent of cases in California, and 58 and 40 per cent respectively in Florida. In

y Mariana Santangan yang di dalam di Managan sanggan dalam IMMUNITY 527

the southern half of the continental United States the occurrence was Flexner bacilli 75 per cent and Sonne bacilli 23 per cent, and in the northern half the percentages were 40 and 60 respectively. The seasonal rise in late summer and early fall is largely accounted for by increases in the number of Flexner bacilli infections.

Immunity. The development of an immunity effective to some degree is indicated by the relative resistance of the resident population of an endemic area to the acute disease which affects recent arrivals, e.g., "acclimatization diarrhea." This phenomenon is well known to residents of temperate climates visiting tropical and subtropical areas.

Antibodies, agglutinins, are formed in response to infection with dysentery bacilli, usually appearing after the sixth day. The titer is relatively low as a rule. The diagnostic significance of agglutinins is somewhat uncertain largely because "normal" agglutinins are common. Normal serum commonly agglutinates Sh. dysenteriae 1 in 1:20 dilution, but a titer of 1:40 or higher is suggestive of infection. Agglutinins for Sh. flexneri occur in much higher titer, as high as 1:150 in normal serum, and the titer is frequently increased in infections with other species of dysentery bacilli. Flexner agglutinin has, then, very little diagnostic value unless it is to high titer, and agglutinins for Shiga and typhoid bacilli are absent. Agglutinins to the Newcastle bacillus, Sh. dysenteriae 2, and E. alkalescens occur only in low titer. Sh. sonnei is often agglutinated to titers as high as 1:50 by normal serum, and, though the titer may occasionally be very high in infection, sometimes little or no agglutinin response is apparent.

The antibody demonstrable as agglutinin, and as protective antibody by the mouse protection test, is apparently unrelated to effective immunity. Consistent with this, vaccine prophylaxis of bacillary dysentery has been almost uniformly ineffective. In this connection it may be recalled that the infection is confined to the lumen of the intestine, intestinal mucosa, and lymphoid tissue as a rule, and in a very real sense remains outside the body. Coproantibody has been demonstrated in bacillary dysentery, but its part, if any, in effective immunity is uncertain.

Unlike infections with typhoid and related bacilli, bacillary dysentery remains a localized infection, and the bacilli rarely penetrate the body beyond the regional lymphatics at the most. An effective immunity is, therefore, one functional at the local level, and present evidence suggests that an essential feature is a stimulation of the immune response in the antibody-forming cells of the lamina propria. Such an immune response is most effectively produced by the local application of antigen, e.g., vaccine by the oral route. The use of killed vaccines in this way has given equivocal results, but a considerable degree of effective immunity is produced by living vaccines.

Two kinds of living vaccines, administered by the oral route, have been used. One consists of bacilli made streptomycindependent and therefore unable to multiply in the absence of the antibiotic. Such vaccines of *Sh. flexneri* have been field-tested in Yugoslavia, and have been found to give significant, but type-specific, protection against the naturally occurring infection.⁵²

The other kind of vaccine is based upon studies of the pathogenesis of the disease and the virulence of the bacilli described above. Two types of vaccine have been prepared with Sh. flexneri 2a and tested in monkeys. The one is an avirulent mutant characterized by inability to penetrate the epithelial barrier, and the other a hybrid strain capable of penetrating epithelial cells but unable to maintain itself to produce foci of infection in the lamina propria. Both have proved to be highly effective in this model in preventing the development of disease in response to challenge inoculation with the virulent parent strain.31 In such immunized animals the virulent strain is unable to penetrate the epithelial barrier and remains in the lumen of the bowel.33 Polyvalent vaccines of hybrid strains of Sh. flexneri 1b, 2a, and 3 and Sh. sonnei I given in two doses by the oral route have been shown to produce a highly effective immunity against challenge with the virulent parent strains.32 The type specificity of the immunity so produced is pointed up by the observed lack of protection against Sh. flexneri 6 challenge, a strain not included in the vaccine.

The type-specificity of the immunity produced by such vaccines would appear to be a limiting factor in their utilization in view of the multiplicity of dysentery bacilli. Almost invariably, however, bacillary dys-

entery in a given area is caused by two or three kinds of bacilli, usually types of *Sh. flexneri* and *Sh. sonnei*. In practice, therefore, immunization against two or three kinds of dysentery bacilli should suffice to control a very large portion of naturally acquired infections.

Chapter Twenty-three

THE CHOLERA VIBRIO AND RELATED FORMS

Although Asiatic cholera has doubtless smoldered endemically in parts of India for many centuries, the year 1817 marked its first considerable extension beyond the borders of that country. Europe was first invaded in 1831, and since that date a series of great epidemics has carried the disease over a large part of the civilized world. The disease was brought to New York by Irish immigrants during the pandemic of 1832-33 and in the pandemic of 1846-62 invaded the United States via New Orleans (1848) and spread up the Mississippi Valley. The fourth great pandemic, that of 1864-75, affected Asia, Africa, Europe, and America. 125 The causal agent of the disease, the cholera vibrio, was discovered in 1883 by Koch in the intestinal discharges of cholera patients. Similar microorganisms were described by later workers in infected water and elsewhere, and now a number of species are known. In general, however, these other vibrios are nonpathogenic and have been studied in terms of their relation to the cholera vibrio and are, therefore, not particularly well known. Of what is now a fairly sizable group, only a few species are pathogenic: the microorganism discovered by Koch and variously termed Spirillum cholerae asiaticae (Koch), S. cholerae, Vibrio cholerae, the comma bacillus and V. comma (Bergey); certain of the El Tor vibrios; Vibrio fetus, infecting domestic animals; and a vibrio pathogenic for pigeons and guinea pigs, Vibrio metchnikovii.

VIBRIO CHOLERAE41, 119

Morphology and staining. The cholera vibrio is a short, slightly curved and twisted

rod, 1.5 to 3 μ in length and 0.4 to 0.6 μ in breadth. It may occur singly or in chains which have the appearance of short spirals or S-shaped forms (two cells). The straight and spiral threads formed in the pellicle of liquid gelatin cultures are usually regarded as involution forms. Cultures that have been maintained for a long time on agar often lose the curved form and appear as straight rods but resume the more characteristic form when passed through animals. The vibrios are actively motile by a single polar flagellum which is shorter than the flagella of most bacteria. Spores are not formed. The cholera vibrio stains readily with the ordinary aniline dyes and is gram-negative.

Colonies on agar mediums are similar to those of the other enteric bacilli but may be distinguished from those of *Escherichia coli* by their thin, opalescent appearance. They are 1 to 2 mm. in diameter, low, convex, and grayish yellow in color, with a finely granular consistency which is accentuated under low magnification. Some strains are hemolytic on blood agar while others are not (see below).

Physiology. The cholera vibrio is strongly aerobic, and only very sparse growth appears under anaerobic conditions, and then on prolonged incubation. It grows over the temperature range of 16° to 42° C. with optimum growth at 37° C. An alkaline reaction is essential for good growth; the bacteria will grow over a pH range of 6.4 to 9.6 and are usually cultivated at an alkaline reaction, pH 7.8 to 8.0. This marked tolerance for alkali is taken advantage of in the preparation of selective mediums for the isolation of the cholera vibrio, the pH of such mediums usually being about 9.5. They are not nutritionally fastidious and may be

grown in peptone water. Many strains grow on simple synthetic mediums¹³² containing ammonium sulfate as a source of nitrogen, but some require added purines.⁶

The relative resistance of the cholera vibrio, as a gram-negative enteric form, to inhibitory substances such as bile salt, bismuth-sulfite, and tellurite is taken advantage of in the preparation of a variety of selective mediums, liquid for purposes of enrichment and solid for isolation^{100, 113} (see below).

Fermentation reactions are variable, and a number of carbohydrates, including dextrose, levulose, galactose, maltose, sucrose, and mannitol, may be fermented with the production of acid but no gas. Lactose, inulin, and dulcitol are not attacked. Heiberg studied the fermentation reactions of the vibrios at some length and arrived at six fermentative types on the basis of the fermentation of sucrose, arabinose, and mannose which are known as the Heiberg types. Type I is characterized by the fermentation of sucrose and mannose but not arabinose, and contains all of the cholera vibrios and some noncholera varieties. Starch is hydrolyzed.

Both coagulated serum and gelatin are liquefied. Stab cultures in gelatin often develop a small turnip-shaped area of liquefaction at the surface, which by evaporation of the fluid leaves a bubble-like depression. Other vibrios besides the cholera vibrio

produce this same type of liquefaction. Growth in milk does not produce any visible change for some time, but a slow peptonization without coagulation appears on continued incubation. Hydrogen sulfide and indol are produced, and nitrates are reduced to nitrities. The addition of sulfuric acid to a culture of the cholera vibrio in nitrate-peptone broth results in the development of a red color—the so-called cholera-red reaction. This is the nitroso-indol reaction and is given by any bacterium, the colon bacillus for example, that both reduces nitrate and produces indol. Other vibrios give this reaction also.

The resistance of the cholera vibrio to various injurious influences is not great. It is killed by moderately high temperatures (10 minutes at 55° C.) and is destroyed quickly by chemical disinfectants. It is particularly sensitive to drying; if a drop of broth culture be dried on a slide, the vibrios are all dead in about two hours. It does not survive long in association with the ordinary saprophytic bacilli of soil and water, and whether it is able to multiply outside the body in impure water is uncertain. Upon the surface of vegetables and fruits kept in a cool, moist place, the vibrios may remain viable for from four to seven days.39 The slight resistance of the cholera vibrio, especially its sensitiveness to drying, explains the rapid and complete disappearance of cholera in once infected localities and also the circumstance that the disease is rarely, if ever, airborne.

Cholera vibrio biotypes. The foregoing description is that of the "classic" cholera vibrio as isolated by Koch and persisting until relatively recently as the predominant, if not exclusive, cause of cholera. Particularly within the last decade it has become clear that, although the general character of the cholera vibrios as described above holds true, causative vibrios occur as a number of differentiable biotypes.

Figure 119. Flagella of vibrios. Left, Vibrio cholerae; right, a paracholera vibrio. × 2000. (Kral.)

At the turn of the century vibrios were isolated from persons passing through the quarantine station at Tor, some of which were immunologically indistinguishable from *V. cholerae* (see below) but differed in that they produced a soluble hemolysin. These so-called El Tor vibrios were again thoroughly studied at Tor in 1930 and 1931 by Doorenbos. The practical quarantine problem was answered by the general acceptance of their nonpathogenicity.

The question of the pathogenicity of the hemolytic vibrios was raised again by the occurrence of an epidemic of clinical cholera in Celebes in 1937 and 1938. 93, 102, 133 About

400 strains of the vibrio were isolated and found to be immunologically identical with the cholera vibrio but hemolytic, and were termed the Celebes vibrios. Cholera caused by these, or closely similar, hemolytic vibrios recurred from time to time in Indonesia in the 1940's, and by 1961–62 had spread widely in the southwest Pacific area (see below). The consequent greatly increased interest in cholera resulted in much more detailed studies of the vibrios and the development of a number of differential characteristics separating the cholera vibrios into biotypes.

Particular interest has centered about the

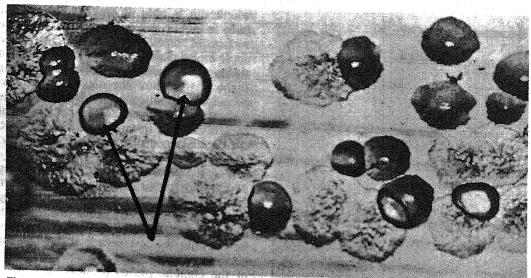

Figure 120. The colonial morphology of *Vibrio cholerae* on bile salt agar in mixed culture with coliform bacilli. The minute, translucent, raised colonies of the cholera vibrio contrast with the roughened appearance of coliform bacillus colonies in the presence of taurocholate. \times 10.

hemolytic activity, and at present soluble hemolysin and blood plate hemolysis are distinguished. The test for the former consists essentially in the incubation of broth culture of the vibrios with a suspension of sheep or goat erythrocytes and, as originally applied, was known as the Greig test. There are a number of variables, e.g., the requirement for calcium, the inhibitory effect of sodium chloride, erythrocyte species, and incubation times and temperatures, and the conditions affecting the test have been studied and a standard method described.36 Blood plate hemolysis is of the β -type, and some strains produce a discoloration known as hemodigestion. The other characteristics differentiating the biotypes are sensitivity to type IV phage, 106 chicken cell agglutination,47 the Voges-Proskauer reaction, and polymyxin B sensitivity. 72, 126 The last is determined with 50 unit discs on nutrient agar: classic cholera strains are sensitive and the so-called El Tor stains resistant.

On the basis of such characterization, a number of biotypes occur^{25, 27, 28} with resulting confusion in nomenclature. Feelev³⁵ has introduced a system with the definition of biotypes designated by number, and these are shown in the accompanying table. It is evident that the occurrence of intermediates between the "classic" and El Tor vibrios has removed the distinction from these terms. though they continue to enjoy some popular usage in which vibrios other than the "classic" types are called El Tor, and the biotypes are considered to be varieties of V. cholerae. As yet the epidemiological significance of such biotypes appears to be limited to a general differentiation of the "classic" type from the others, and the stability of the

differential characteristics remains somewhat uncertain.^{28, 64, 109, 127}

Toxins. Unlike the dysentery bacilli, the cholera vibrio remains within the lumen of the bowel, with no evidence of penetration of the epithelial barrier. This is taken to indicate that the disease is essentially an intoxication, a supposition which has been supported by the demonstration that, under experimental conditions, the manifestations of infection may be wholly accounted for by the activity of cell-free toxin. 10 The question of the absorption of toxic substances remains largely unresolved although in the opinion of many workers23 the observed histopathology is not entirely attributable to dehydration and acidosis characteristic of the disease (see below). Interest has centered largely about the local manifestations of the disease, and the presumably local effects of toxin, in the altered water and ion movement resulting in the purging diarrhea and concomitant loss of fluid and electrolyte.

The cholera vibrios form a multiplicity of toxins, some of which are separable into groups, or types, on the basis of their occurrence in the cell and in culture, their heat stability, and their dialyzability. The toxic action of each type is demonstrable in more than one way, and it is not yet clear whether this is an artifact of assay methods, or whether differentiable toxins occur within each type. These toxins are summarized in the accompanying table.⁹

Type 1 toxin is apparently endotoxin of the Boivin type, *i.e.*, extractable in trichloracetic acid solutions, glycols, etc., and acts as a lethal toxin in the mouse and chick embryo. There seems to be no evidence that

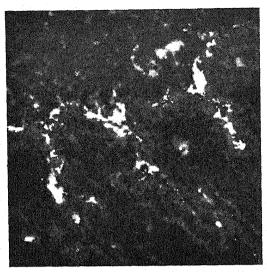

Figure 121. Fluorescent antibody-stained frozen section of the small bowel of a guinea pig infected with cholera. The vibrios are apparent in the lumen, sticking to the epithelial cells at the villus tips, extending into the crypt areas, and filling indentations of the epithelium. Failure to penetrate the epithelium is evident. (LaBrec.)

it is active at the local level in the bowel, but it may be absorbed as a consequence of permeability alterations by other toxins to contribute in an as yet undefined way to the pathogenesis of the disease.⁷⁷

The other two types of toxin appear to be active at the local level. The dialyzable heat-stable toxin of type 3 markedly inhibits the active transport of sodium in anurian epithelium in vitro^{57, 73} and in vivo.⁸⁹ The hypothesis that such inhibition of the sodium

pump is responsible for the diarrhea is an attractive one, and has been strongly advocated. 114 It has been found, however, that type 3 toxin freed of other toxins as a dialysate does not induce the required changes in water and ion movement in experimental models, 15, 89 a finding that negates its primary role in the pathogenesis of the disease.

In contrast the toxins of type 2, the socalled cholerigenic toxins, produce water and electrolyte loss - as in diarrhea in the infant rabbit and intraluminal fluid accumulation in the ligated ileal loop of the rabbit (see below) - in crude form or when separated in purified form from toxins of types 1 and 3. The activity is exotoxic in that it is found in the liquid culture supernatants. As assayed in the infant rabbit, type 2 toxin has been termed choleragen (formerly procholeragen A).48,49 The composition of the intraluminal fluid in the rabbit ileal loop closely resembles that of the human cholera stool,90 and liquid culture supernatants have been shown to produce cholera-like disease in man.4 A toxin of similar properties, designated the permeability factor, produces an intradermal reaction characterized by an increased capillary permeability19,20 resembling that observed in the bowel tissue in the human disease. Type 2 toxin is also demonstrable by cytopathic effects, swelling, accumulation of intracellular lipid, detachment, and lysis on mammalian cells in culture. 120 This toxin, or group of toxins, is produced by the "classic" and other biotypes of the vibrio, but relatively few strains are found to be highly toxigenic in vitro.

^{*}Endotoxin.

^{†&}quot;Cholerigenic" toxins.

[‡]Active transport inhibitors.

Hemolysin. The hemolysin produced by some biotypes of *V. cholerae* occurs, together with other toxins, in liquid culture supernatants.¹³⁷ It has been studied in highly purified form¹³⁸ and may be a lecithinase.⁹⁴ It is apparently unrelated to the pathogenesis of the disease produced by these microorganisms,¹³⁹ but the occurrence of antihemolysin in patients' serms may be a useful serological method for retrospective diagnosis.⁴³

Mucinase. The cholera vibrio and related forms also produce mucinase activity which desquamates the intestinal epithelium of the guinea pig in vitro and is titrated in vitro against ovomucin. 16, 78 More than one serologically different mucinase is produced by V. cholerae, and potent mucinases are produced by noncholera vibrios, so that the relation of this activity to the pathogenesis of the disease is doubtful. 53

Antigenic structure. The first demonstration of bacterial agglutination with homologous immune serum by Gruber and Durham in 1896 was the agglutination of the cholera vibrio and the typhoid bacillus. It was soon apparent that the agglutination reaction was specific, and it has been used for the identification of the cholera vibrio since. The antigenic structure of the cholera and related vibrios has, therefore, been of considerable interest in connection with the differentiation of *V. cholerae*.

The vibrios contain both somatic heatstable O antigens and flagellar heat-labile H antigens. The type-specific antigens are O antigens, and a number of serological groups have been established; the cholera vibrio and certain of the El Tor vibrios (see below) fall into that designated O group I.

It was first shown by the Japanese workers that three serological types of the cholera vibrio may be differentiated on the basis of the specificity of the heat-stable O antigens. These are the "original," J, or Inaba type;

the Hikojima, "middle", or "intermediate" type; and the "variant," F, or Ogawa type. For many years only the Inaba type was found in India, but now the Ogawa type is often observed. The Hikojima type appears to occur primarily in China together with the Ogawa type and Inaba type. Some have questioned the validity of the Hikojima type, but there is no doubt that it occurs. 60 The distribution of these types has no epidemiological significance, at least in India, and, in fact, their stability is uncertain. Shrivastava and White¹²⁹ found that cultivation in the presence of heterologous antiserum results in conversion of Ogawa strains to Inaba, and of some Inaba strains to Ogawa. Other workers⁵ have found, however, that the change seems to occur in only one direction; i.e., cultures of the Ogawa serotype tend to throw off Inaba variants.

A detailed analysis of the O and H antigenic structure of the cholera and related vibrios showed that a group-specific O antigen, designated A, is shared by all vibrios of group I, and that the Japanese types are determined by subsidiary O antigens, B and C, and are arbitrarily designated type-specific. It was suggested that the Japanese types be indicated by their antigenic formulas, i.e., Inaba as type AC, Ogawa as type AB, and Hikojima as type ABC. Vibrios containing the group antigen but lacking these type-specific antigens have been found and thus constitute a new type. Additional antigens making up a variety of serotypes have been described. 14, 58, 134 The occurrence of certain antigenic types has been questioned but the low titer antiserums used prevented their demonstration: type A, for example, has been observed among strains isolated in Bangkok in 1958-1959. Antigens other than the group- and type-specific antigens are demonstrable also by the application of other methods of assay such as gel diffusion.67, 68, 99 The H antigens, designated by Arabic numerals,

and other components of the O antigen are shared by the O group I vibrios with vibrios of other O groups.

Antigens other than those demonstrable by the conventional agglutination-agglutinin absorption method of antigenic analysis were first observed as giving rise to protective antibody effective in the mouse and guinea pig enteric infection assay and as producing antibody demonstrable in the passive hemagglutination reaction and by complement-fixation.¹¹ Gallut⁶¹ separated this antigenic complex as a precipitating antigen by phenol extraction of specific polysaccharide-containing antigens. This complex, designated nonagglutinogen antigen, or NAA, is shared in part with non-cholera vibrios.

A curious terminology has crept into the cholera literature with respect to agglutination; it is said that a strain which is agglutinated by specific antiserum is "agglutinable" while those vibrios which are not agglutinated by cholera antiserum are called "inagglutinable" despite the fact that they are readily agglutinated by homologous antiserum. These are referred to as the nonagglutinating vibrios, or NAG vibrios.

The cholera vibrios are serologically related to Brucella, and this has given rise to positive Brucella agglutination tests in persons who are not infected with Brucella but have been immunized with cholera vaccine. Gallut⁵⁹ has shown that the common antigens are the C and D antigens of the cholera O antigenic complex. An antigenic relationship of certain vibrio strains to coliform bacilli of the Bethesda group has been described also.⁹⁵

Variation. The cholera vibrio is well known for its tendency to develop bizarre involution forms. These are found not only in old cultures and cultures grown under somewhat adverse conditions, such as increased salt concentrations, but are also produced by the inclusion of substances such as glycine or alanine in the medium. Such changes in morphology are also associated with the usual type of S-R dissociation which occurs readily under the influence of bacteriophage, lithium chloride, etc., the rough variants showing distinctive colonial character, spontaneous agglutination in salt solution, and so on.

The immunological changes associated with the S-R dissociation have been studied in some detail by White. 141 He has found

that four groups of rough variants are immunologically distinguishable, and his group A appears to correspond to the group I of Gardner and Venkatraman. Further degeneration to the so-called ρ variants results in a loss of specific O antigen. An independent type of variation, rugose-nonrugose, may be induced, and the rugose strains of S, R, and ρ variants contain an O antigen that is common both to members of group A and to vibrios of other groups. A somatic protein antigen has been isolated by White which is common to all known variants and shows wide cross-precipitin reactions throughout the vibrio group, although it appears not to be concerned in the agglutination reaction.

Classification. While the cholera vibrio is set apart taxonomically from the Enterobacteriaceae as a genus of the tribe Spirillaceae, it is often, perhaps subconsciously, considered with the enteric bacilli. Doubtless this is attributable largely to the kind of disease it produces, but the cholera vibrio does resemble the anaerogenic enteric bacilli, such as Shigella, by its fermentation of glucose via the glycolytic pathway, by its having sufficient homology to share the R-factor with enteric bacilli. 85 etc.

Classification at this level has not been a matter of great concern, but both theoretical and practical considerations have entered into the characterization and nomenclature of the cholera vibrios. The name Vibrio comma of the Bergey classification has never gained acceptance outside this country, and cholera has occurred exclusively elsewhere for many years. The name Vibrio cholerae is almost universally used, and is now internationally accepted. 122

The status of the biotypes described above has not yet been formally settled. The separation of Feeley's type 3 (see above) as a different species, *Vibrio eltor*, is advocated by some, but is considered by others to be no more than a biotype⁷⁴ or variant³⁸ of *V. cholerae*. It seems probable that the latter view will prevail.

Pathogenicity for man.^{23, 86} The causal connection between cholera and the microorganism discovered by Koch has been demonstrated by a number of laboratory accidents. One of the first occurred in Koch's laboratory, and other infections resulting from the accidental swallowing of cultures of the cholera vibrio have been noted since. In one instance the swallowing

was deliberate; Pettenkofer and Emmerich voluntarily swallowed a small quantity of broth culture of "Koch's vibrio" and as a result developed cholera.

As indicated above, substantially identical clinical disease is produced by the several biotypes of V. cholerae. In addition, other unrelated vibrios are also associated with diarrheal disease. $^{97, 98}$ Such vibrios gave a positive reaction in the infant rabbit, and others, including certain water vibrios, initially unable to infect the infant rabbit, did so after animal passage. 32

Both laboratory cases of cholera and those cases contracted naturally in the course of epidemics are marked by great differences in the susceptibility of different individuals. The possible relation of the malabsorption syndrome, with leaf rather than finger patterns of villi, the amount of hydrochloric acid in the stomach, the diet, and similar factors have all been of interest in this connection, but as yet none has been clearly associated with susceptibility to infection.

The incubation period is short; it is usually given as three to five days but may occasionally be as short as 24 hours. The sequence of events appears to be as follows: The vibrios pass the barrier of gastric acidity in sufficient numbers to set up a focus of infection in the small bowel. Toxin, presumably the type 2 toxin described above, is elaborated, and fluid and electrolytes are rapidly lost in the resulting purging diarrhea. 115 This initial reaction is sometimes referred to as the first stage of the disease. The rice water stool is innocuous in odor and appearance; is a transudate in nature, consisting of plasma minus protein; and contains flakes of mucus, shed epithelial cells, and enormous numbers of vibrios. With continued loss of water and bicarbonate, marked dehydration and metabolic acidosis become prominent features, and the affected person is in a state of collapse. This is referred to as the second stage of the disease, characterized by circulatory failure, subnormal temperature, and anuria. In contrast to bacillary dysentery, the mucous membrane of the bowel remains intact.64, 131 Uncommonly, the infection may not result in diarrhea but give rise to the form of the disease known as cholera sicca; an occurrence taken as evidence of a generalized intoxi-

Treatment is symptomatic and consists

of the replacement of fluid and electrolytes. Usually there is acidosis, and patients literally minutes away from death may be saved by rapid (as much as 1 liter in 10 minutes) intravenous administration of isotonic bicarbonate solution. Thereafter the patient is rehydrated with alkali, bicarbonate or lactate, or saline, and is maintained on intravenous fluid to balance the loss until the diarrhea stops and renal function is initiated. Usually 20 to 25 liters are required, but in exceptional instances as much as 70 liters have been required. Potassium loss may be sufficient to result in cardiac difficulties, and replacement of potassium as a constituent of the rehydration fluid or by mouth as green cocoanut water is more often required in pediatric than adult cholera.92

Antibiotic therapy of cholera has, in general, been without effect other than a reduction in the time during which vibrios are excreted. Tetracycline, however, markedly reduces fluid requirements. 71, 135 Other antibiotics and the sulfonamides, to which the vibrios are sensitive *in vitro*, show little or no such effect; the mechanisms involved are not as yet known.

The case fatality rate in untreated cases is 50 to 60 per cent, although it may be less in some epidemics, ¹⁰⁴ perhaps 10 to 20 per cent in treated persons, and may be reduced to 1 per cent or less under ideal conditions of therapy.

Carriers. On recovery the vibrios disappear rapidly and are discharged for only a short time. In the series of 200 cases studied by Ying, 98 per cent were negative by the end of the second week, only a few giving positive cultures as late as the third and fourth weeks. In a study of 113 continuously observed cases, Gilmour⁶⁹ found that 71.6 per cent were negative after the first week, 89.3 per cent after two weeks, and 98.1 per cent after three weeks, with maximal periods of intermittent excretion of 20. 21, 23, and 25 days. Similar results were observed in the Egyptian epidemic of 1947, with 96 per cent of patients negative after three weeks and with a maximal period of intermittent excretion of 39 days.

It is probable that causal carriers occur during epidemics, and such a carrier state was demonstrated by Egyptian workers during the 1947 epidemic. A carrier incidence of 2 to 4 per cent in contacts was observed, but Gohar and Makkawi found

that it did not persist more than 10 days. More recently, similar results have been obtained in the Philippines and adjacent areas and in Bengal. In the Calcutta carrier study, it has been found that the infection persists in asymptomatic carriers during interepidemic periods, when only occasional cases occur, and in East Pakistan, where one study¹¹² showed that in 49 infected households the infections were nonclinical in 17. In the Philippines, asymptomatic infections or ambulatory cases functional as carriers have been observed repeatedly since infection was reintroduced in 1961.

For many years it was believed that no chronic carrier state occurred in cholera, a conclusion based in part on the failure to find such carriers by bacteriological examination and in part on epidemiological evidence such as the failure of cholera to occur in Cevlon in spite of the large annual influx of migratory workers from India, where cholera persists in endemic form. 118 With the spread of infection with biotypes other than the "classic" vibrio, e.g., El Tor types, it has become clear that a chronic carrier state may occur. One carefully studied individual in the Philippines has continued sporadically to excrete the vibrio biotype with which she was originally infected for a period of several years, but how widespread such a chronic carrier state may be is as yet uncertain. The method of purging to detect the carrier state may be useful in this connection.63

Bacteriological diagnosis.^{12, 101} As indicated above, the vibrios are present in the rice water stools in very large numbers and can usually be isolated from fresh specimens without difficulty. At times they are present in sufficient numbers that they can be found in stained smears, preferably made from a flake of mucus. The fluorescent antibody technique has been applied to the rapid identification of the vibrios.⁴⁶ Direct darkfield examination of the rice water stool specimen with and without antiserum permits rapid provisional diagnosis as immobilization of the cholera vibrios in the presence of specific antiserum.³

Both enrichment and direct streaking of agar mediums are used for cultures. For enrichment a few drops of the stool are added to a tube of alkaline (pH 8.0 to 9.0) peptone water. The vibrios grow much more rapidly than the other intestinal bacteria, and after six to eight hours' incubation they

form a thin film of growth on the surface of the medium which can be smeared and stained, and streaked on agar.

A number of agar mediums have been used for isolation of the cholera vibrio, including starch-phenolphthalein agar and the alkaline blood medium of Dieudonné. Bile salt agar, nutrient (meat extract) agar at pH 8.0 and containing 0.5 per cent sodium taurocholate,34 is one of the most useful and satisfactory mediums for primary isolation; some workers believe that the medium is improved by the addition of gelatin. On 24 hours' incubation the cholera vibrios grow as small to moderate size translucent smooth colonies sharply differentiable from the roughened colonies of coliform bacilli. Oblique light microscopy is considered by many to facilitate recognition of the typical colony.87 The microorganisms are identified by slide agglutination in O group I antiserum and typed in monospecific Inaba and Ogawa antiserums if desired. With clinically typical cholera in an epidemic this is sufficient identification.

The isolate may also be typed with monospecific Inaga and Ogawa antiserums, the Heiberg type being shown by fermentation tests, and the biotype determined by application of the various differential criteria described above. Tests other than O group I agglutination are usually carried out at a central or reference laboratory.

Epidemiology.^{40, 80} As in the other enteric infections, the connecting link in the dissemination of cholera is between infected feces and the mouths of susceptible persons. In consequence, the disease is frequently waterborne and may be transmitted by any food ordinarily consumed in the raw state. The quantitative importance of contact infection is not known. Cholera differs from the other enteric diseases, however, in the highly explosive character of the outbreaks, which is attributable to the short incubation period, the high case fatality rate, and its rapid disappearance when the outbreak has subsided.

In a sense cholera is one of the easiest to control of the highly contagious diseases, for it cannot spread when sanitary facilities, i.e., sewage disposal, water supply, etc., are in efficient operation. A striking instance of this was reported in the Balkan War in 1913 in which infection was widespread in the Bulgarian Army around Sofia, but cases in the capital were largely imported and the disease showed little tendency to spread

there; Sofia was efficiently sewered and had an excellent water supply.

Endemic foci. Cholera persists in interepidemic periods in foci of endemic infection. Endemic areas are adjacent to rivers and are low lying and densely populated. In such areas tank water and other stored water often contain cholera and related vibrios.1,2 It is probable that the infection persists in contact, and possibly chronic, carriers, and as a small number of human cases of the disease, which occur continuously between epidemics. 17, 26 The use of phage typing in tracing sources of infection has not as yet been too productive, for there is considerable overlap in sensitivity, and only a few phage strains have been used. 105 It is not known why this occurs in some areas but not in others.

The classic focus of endemic infection is in Bengal, extending from the Ganges and Brahmaputra deltas into Assam and Bihar. There is also a focus of infection in Burma in the Irrawaddy delta, and possibly also in parts of the Salween delta. Cholera has occurred in Nepal for many years, and this area is also suspected of being an endemic focus. The disease occurs in China, but precise information as to its prevalence and possible endemicity is lacking. Following the spread of the so-called El Tor biotypes, infection has persisted in endemic form in a number of invaded areas in southeast

Asia and in the Philippines, but it is too early to say whether such areas have become permanent foci of infection.

Epidemic spread. Each year the disease occurs in epidemic form, first in the endemic areas such as Bengal, beginning in February. The peak is reached in April and May in Bengal, just before the beginning of the monsoon season, and there is a remarkable correlation between relative humidity and the incidence of cholera. 124 In Bengal a small secondary peak occurs in December; the seasonal incidence of the disease in that area is illustrated in the accompanying figure.

The disease extends from these foci each year, reaching a peak in Punjab, in July and August, and in Uttar Pradesh in the spring, and spreads through central India to Madras and Bombay.

Its spread beyond these areas into Europe and the Western Hemisphere has occurred as a series of pandemics, as described at the beginning of this chapter. The quarantine stations at Tor and Basra function to prevent the spread of infection into the Middle East, although cholera occurred in epidemic form in Egypt in 1947, coincident with the British evacuation of India. The traditional route of spread to the west has been via Afghanistan into the Middle East and Eastern Europe, and this spread is difficult to control because of the continuous

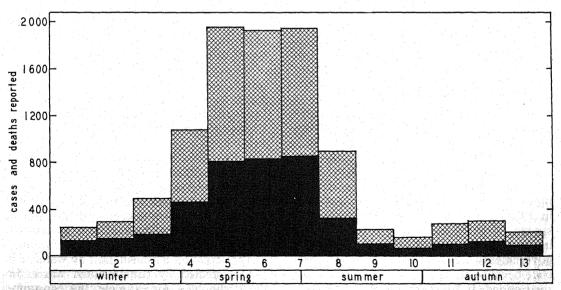

Figure 122. Representative incidence of cholera in West Bengal, shown as the mean numbers of cases and deaths reported by four-week periods. (Data from Epidemiological and Vital Statistics Reports, World Health Organization.)

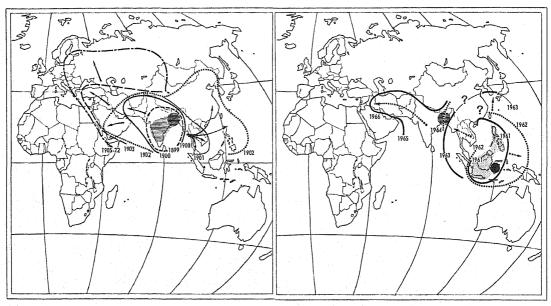

Figure 123. The epidemic spread of cholera. Left, the classic route of spread through Afghanistan and the Near East to Europe and Africa as illustrated in the sixth pandemic, 1899–1922. Right, the spread of cholera during the period 1961–1966, which appears to approximate the initial stages of a pandemic. (World Health Organization.)

operation of smuggling and similar unregulated traffic. Although cholera has not occurred in Western Europe since the latter part of the nineteenth century, and not in European Russia since 1926, an outbreak occurred in the Ukraine in 1943.⁵⁶

El Tor cholera.37 The occurrence of cholera caused by biotypes other than the "classic" cholera vibrio in Indonesia in the late 1930's has been noted above. The infection spread from the initial focus of infection in Celebes to other parts of Indonesia, and to Sarawak and possibly Kwantung, and was also found in India as early as 1945.110 Beginning in 1960-61 it developed into epidemic form, appearing in Macao and Hong Kong,91 probably from Kwantung, progressed to the Philippines,30,136 spreading through the western Pacific area to Borneo. Loas, Thailand, Cambodia, etc., and into India. 108 Further spread has followed the traditional route into the Middle East to produce epidemics in Iran in 1964 and Iraq in 1965. It is difficult to ascertain the true spread of the disease, since it comes under international quarantine regulations, and governments are reluctant to admit its presence because of the imposition of quarantine restrictions. It has been suggested that extension of the disease is characteristic of the beginning of a world-wide pandemic,

and it has been a cause of considerable concern.

Because of quarantine restrictions, what continues to be popularly called El Tor cholera was considered to be "choleriform enteritis" until this terminology became untenable, and international quarantine regulations were modified in 1962 to eliminate the difference in control measures between cholera and El Tor cholera.

The initial differentiation of the El Tor biotypes was based on hemolysin formation,42 but with the persistence of infection in the invaded areas, the hemolytic characteristic has tended to disappear, with the appearance of "nonhemolytic El Tor" in Indonesia, 103 and current isolates in the Philippines tend to be nonhemolytic; insensitivity to phage type IV appears to be a more stable character. The disease produced is clinically indistinguishable from classic cholera, the treatment is the same, and vaccines prepared from the "classic" biotype show complete cross-protection against El Tor challenge under experimental conditions.116

The infection is transmitted by water and foods infected by contaminated water. In the Philippines, for example, the consumption of contaminated shrimp apparently was responsible for the initial epidemic.

On invasion of an uninfected area, the disease tends to occur in all age groups, but with persistence of the disease it is found more often in children, and pediatric cholera tends to characterize the disease in endemic areas. It tends also to be a contact infection under these circumstances, although waterborne and foodborne outbreaks occur as in Hong Kong four years after the initial epidemic.⁵⁰

Immunity. Recovery from an attack of cholera confers an immunity to subsequent infection, but the quality of the immunity is not definitely known; it appears to be of limited duration, perhaps six months to a year. There is a rise in serum antibody. agglutinin, vibriocidal antibody,44 and antitoxin. According to the most recent studies, agglutinin reaches a peak of perhaps 1:1280 and vibriocidal antibody 1:50,000 to 1:70,000 10 to 12 days postonset,128 and antitoxin about 2000 units per ml. at two weeks.82 Coproantibody is produced also. but may not parallel serum antibody.55 It is not clear how such serum antibody titers may relate to an effective immunity to the disease but, under appropriate conditions. they may have diagnostic value. It may be noted, though, that cross-reaction with Brucella antigens may result in cholera vibrio agglutinin titers in brucellosis serums, and that very high-and inexplicablecholera vibriocidal antibody titers are occasionally observed in serums from persons having no contact with cholera vibrios.

Vaccines. The vaccines currently used for prophylactic immunization consist of saline suspensions of killed vibrios, not less than 8000 million per ml., and are usually bivalent, consisting of equal numbers of the Inaba and Ogawa serotypes. One vaccine is put up in freeze-dried form, and that prepared at the Haffkine Institute is a whole culture vaccine of vibrios grown in casein hydrolysate medium. Immunogenic potency is assayed by the active mouse protection test; i.e., immunized mice are challenged with mucin-vibrios by the intraperitoneal route (see below). 117 Immunization of man is commonly accomplished by a course of two doses of 1 ml. each, given a week apart by the subcutaneous route, and the booster inoculation, required at sixmonth intervals by international regulation, is 1 ml. subcutaneously or 0.1 ml. intrader-

The validity of the mouse potency test is

questioned perennially, and field tests suggest some small degree of efficacy²⁹ which may or may not be correlated with the mouse test. The most recent of such field tests are those carried out in Calcutta under the auspices of the World Health Organization. in the Philippines, 121 and in East Pakistan by the Pakistan-SEATO Cholera Research Laboratory. 111 The vaccines tested varied widely, the most effective being the CRLtested vaccine, which gave about 75 per cent protection in an endemic area. Other immunizing preparations, notably purified lipopolysaccharide antigen,83,140 have been suggested, but as yet have not been adequately field-tested.

The pathogenesis of the disease, i.e., the production of symptoms, even though the vibrios remain in the lumen of the bowel and out of contact with circulating antibody. has been taken to suggest that coproantibody plays a significant part in immunity. Coproantibody response is best obtained by local application of antigen, e.g., by the oral route,⁵⁴ and under experimental conditions appears to be associated with an antibacterial immunity, 13 but oral antigen has not been field-tested in man. An attenuated living antigen would presumably be most effective, and such vaccines have been suggested. 107 The appearance of antitoxin in response to infection and the observation that asymptomatic contact carriers have high antitoxin but low antibacterial antibody titers (i.e., they tolerate the infection without symptoms) suggest that an antitoxic component may be a significant element in an effective immunity.

Pathogenicity for lower animals. The cholera vibrio appears to be exclusively a parasite of man, and naturally occurring infections, as distinct from contamination as of crustaceans, has not been described. Experimental infections have been of interest in connection with the assay of immunogenic potency of vaccines and as models simulating to a greater or lesser degree the human disease.

Experimental enteric infection of the guinea pig was described by Koch, who fed the animals broth cultures of the vibrios, as a part of the evidence for the etiological relation of the vibrio to the disease. The infection may be asymptomatic, but a fatal infection may be produced with streptomycin-resistant vibrios in animals treated with the antibiotic.⁵² The suckling rabbit

may be infected by the oral route, as shown by Metschnikoff at the turn of the century, and this infection was studied in detail by Sanarelli in the 1920's. The guinea pig may be infected by intraperitoneal inoculation, and a fulminating fatal bacteremia may be produced in the mouse by the intraperitoneal inoculation of vibrios in mucin. This last is used extensively in the assay of immunogenic potency of vaccines as indicated above. A fatal infection may be produced in the embryonated egg, 45, 65, 66 and the embryo is also killed by cell-free toxins of type 1.

In the 1950's, De and his co-workers showed that infection may be produced in ligated segments of the small bowel of the adult rabbit by direct inoculation,24 a technique which has been used with enteropathogenic coliforms and Shigella as described elsewhere (Chaps. Twenty and Twenty-two). Subsequently De showed that the ligated loop reaction can be produced with cell-free lysates of the vibrios or with liquid culture supernatants.22 At about the same time. Dutta and his associates restudied the infant rabbit infection, and showed that diarrhea, often fatal, could also be produced in these animals with similar cell-free preparations.33 Russian workers have made some use of the infection in the ligated ileal loop in the guinea pig. Quite recently Sack, Carpenter, and their colleagues have found that an enteric infection may be produced in the dog and that cell-free preparations give similar reactions: the resultant disease closely resembles that in man but the required doses are relatively large.

Animal models. Of these experimental infections, the enteric infections have been of greatest interest as models simulating to a greater or lesser extent the human disease, and the production of essentially identical reactions with cell-free material has shown the overriding importance of toxins. The infant rabbit model has been used extensively by Finkelstein and his co-workers in their study of the cholerigenic

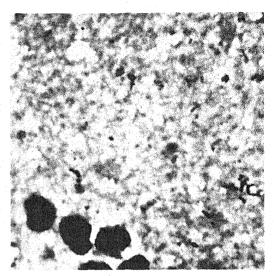

Figure 124. Vibrio cholerae in peritoneal exudate of a guinea pig. Note the swollen and aberrant forms. Gram stain; × 1250.

toxins described above, and the use of this model by others has made possible the differentiation of enterotoxic and sodium transport-inhibiting toxins. The infant rabbit model cannot be used for active immunization studies, but it has been applied in the assay of passive protection.⁹⁶

The reaction in the rabbit ileal loop model to cell-free toxin resembles the human disease in the histopathology produced,⁵¹ and in the toxin-induced water and ion movement indicated by the composition of the intraluminal fluid.90 It can be precisely quantitated to allow the titration of toxin and antitoxin,81 and the antitoxin titration can be modified as an interference reaction for the titration of toxoid.82 It has been found that the ileal loop reaction involves three separable toxins: that which induces fluid accumulation; type 1 toxin, which is absorbed in consequence of altered bowel permeability; and type 3 toxin, which inhibits active sodium transport. The antitoxin titrated is that to the first of these, which has been prepared in purified form. 18, 76

Other Vibrios

For the most part as an adjunct to the study of the cholera vibrio, a considerable number of vibrios have been isolated from water and from the feces of individuals

suffering from mild diarrheal disease, socalled cholera nostra. Some of these have been given place names such as V. danubicus, V. ghinda, and V. massauah. A phosphorescent vibrio, *V. phosphorescens*, has been isolated from water, and *V. proteus* from human feces. All of these differ immunologically from the cholera vibrio, *i.e.*,

belong to O groups other than I.

A number of other vibrios are known which produce disease in animals but which are apparently not pathogenic for man. Vibrio metchnikovii was isolated in 1888 from fowls suffering from an epidemic disease resembling fowl cholera. It closely resembles the cholera vibrio morphologically and physiologically and is highly pathogenic for guinea pigs and pigeons, while the cholera vibrio is not pathogenic for the latter. It differs from V. cholerae immunologically and is neither agglutinated nor lysed by anticholera serum.

An epidemic disease of carp and other fishes caused by a vibrio designated V. piscium has been described by David. The vibrio resembles the cholera vibrio morphologically and is immunologically re-

lated to it.

Vibrio parahaemolyticus. 142 A form of foodborne infection prevalent in the summer in Japan, and associated with the consumption of uncooked fish and shellfish (shirasu), has been found to be attributable to a halophilic vibrio, V. parahaemolyticus. In peptone water culture the vibrios form protoplasts, and they grow well in 7 per cent sodium chloride, but not in 10 per cent solutions. They are separated into two groups, 1 and 2, on a physiological basis and contain a number of differentiable O antigens. The vibrios of group 1 appear to be pathogenic, while those of group 2 are not. They are found in sea foods, in as many as 13 per cent of the samples in the summer months, and in healthy human subjects, as well as in some 30 per cent of cases of acute gastroenteritis. These microorganisms are quite unrelated to the cholera vibrios.

Vibrio fetus. A microorganism designated Vibrio fetus infects cattle, sheep, and goats to produce abortion in pregnant females and an essentially symptomless infection in males. The vibrio differs sharply from the cholera and paracholera vibrios in that it requires enriched mediums for growth, is relatively inactive biochemically, 88 and is antigenically distinct, falling into a number of serotypes. The naturally occurring disease is closely reproduced in the pregnant female guinea pig. The infection is transmitted by contact, and in cattle 8, 75 and

goats, but apparently not in sheep,⁷⁹ the infected male acts as a carrier, spreading the infection by breeding. In the female, agglutinating antibody occurs in the cervicovaginal secretions to considerable titer and is considered to be diagnostically reliable in contrast to irregular serum agglutinin. A few human infections have been reported,^{84, 130} some of which resemble brucellosis; the infection is a generalized one and the vibrios are found in the blood.

Two other vibrio species are responsible for diarrheal disease of certain domestic animals. *Vibrio jejuni* infects calves; it differs from *V. fetus* culturally and serologically and is nonpathogenic for guinea pigs. *Vibrio coli'* is the etiological agent of swine dysentery.³¹

Chapter Twenty-four

BRUCELLA

Undulant Fever; Contagious Abortion of Cattle

In 1887 Bruce, while investigating the human disease known as Malta fever, Mediterranean fever, or undulant fever. discovered a microorganism in the spleen in fatal cases of the disease which he designated Micrococcus melitensis. A disease of goats transmissible to man, this affection not only is common on the island of Malta, where British garrisons have been often seriously affected, but occurs also on neighboring islands and on the shores of the Mediterranean Sea, and has been occasionally reported from India, South Africa, the Philippines, and the West Indies. It was first brought to attention in the United States about 1911.

In 1897 Bang, in Denmark, isolated a microorganism responsible for contagious abortion in cattle, an affection now commonly known as Bang's disease, which he termed *Bacillus abortus*. The isolation and cultivation of this bacterium in the United States were first recorded by MacNeal and Kerr in 1910.

These two diseases, one primarily of goats and secondarily of man, and the other, one of cattle, were long studied quite independently, and apparently no connection between the two was recognized prior to the work of Evans in 1918. She demonstrated the remarkably close morphological, cultural, and serological relationship existing between these bacteria, which are now recognized as being intimately related to one another.

In 1914 Traum isolated from fetuses prematurely expelled from sows a bacterium which is now known to be closely related to the bacterium of Bang's disease and that of undulant fever. Regarded as three species, these bacteria have been given the generic name of Brucella and are designated as Brucella melitensis, Br. abortus, and Br.

suis. Infection with these bacteria is termed brucellosis.³

Morphology and staining. The Brucella are small coccoid or short bacillary forms varying from 0.4 to 3.0 μ in length and from 0.4 to 0.8 μ in breadth. Some variability is noted, and both coccoid and bacillary forms may appear intermingled. There is a greater tendency to the coccobacillary form in Br. melitensis than in Br. suis, with Br. abortus intermediate between the two, but no distinction can be made on a morphological basis. The microorganisms usually occur singly or in pairs, and in cultures short chains may be found. The smooth forms are encapsulated but spores are not formed, and these bacteria are nonmotile.

On semisolid mediums the colonies are small, circular, convex, amorphous, smooth, glistening, and translucent. No pigment is formed, but the growth of *Br. melitensis* becomes brown in older cultures, and the browning extends down into the medium. This browning is shown by some strains of *Br. abortus* also.

Brucella may be stained by the usual aniline dyes, but there is a tendency toward irregular staining and, in some cases, bipolar staining. They are gram-negative.

Physiology. The nutritive requirements of these bacteria are relatively complex, and the best growth is obtained on enriched mediums such as liver infusion broth or agar. Brucella have been cultivated on amino acid synthetic mediums; some strains require nicotinamide, thiamin, and pantothenic acid while others require biotin also. A number of chemically defined or synthetic mediums have been prepared which support the growth of Brucella, one of the simplest of which is that of Gerhardt and Wilson¹⁹ containing lactate, glycerol, asparagin (or glutamic acid or histidine), thiamin, nicotinic

acid, pantothenic acid, and biotin together with inorganic salts. No growth occurs at 6°C. or 45°C., and the optimum temperature is 37°C. Neither acid nor gas is produced from carbohydrate mediums, although it may be shown that glucose is utilized to a small extent, and its inclusion generally favors growth. Nitrates are reduced, and growth in milk is accompanied only by slowly increasing alkalinity. Gelatin is not liquefied, and indol is not formed. Urea is hydrolized by *Br. suis*, but not by *Br. abortus* or *Br. melitensis*. The optimum pH is 6.6 to 6.8

Hydrogen sulfide. All three species produce hydrogen sulfide but differ in that Br. suis produces it in abundance, Br. abortus to a lesser extent, and Br. melitensis to only a slight degree. It may be noted that ammonia is produced to a greater extent by Br. melitensis than by the other two species.

Carbon dioxide. These bacteria are aerobic, and Br. melitensis and Br. suis may be grown on primary isolation under the usual aerobic conditions. Br. abortus, however, requires incubation in an atmosphere containing 10 per cent carbon dioxide on primary isolation. Subsequent transfers from the primary growth must be incubated in 10 per cent carbon dioxide, but after a number of transfers Br. abortus adapts itself to ordinary aerobic growth.

Dyes. The species of Brucella show a differential sensitivity to a number of dyes. Thionine and basic fuchsin may be incorporated in liver infusion agar in dilutions of 1:50,000 and 1:25,000 respectively. Br.

melitensis and Br. abortus will grow in the presence of basic fuchsin but Br. abortus will not, while Br. melitensis and Br. suis will grow in the presence of thionine but Br. abortus will not. Crystal violet and pyronine give the same reactions as basic fuchsin, and azure A and safranine O have some utility also. The growth of Br. melitensis is also inhibited in the presence of sodium diethyldithiocarbamate, while that of the other two species is not. Growth inhibition may be tested by the use of dve tablets analogous to the antibiotic discs used to assay antibiotic sensitivity, but higher concentrations are required than when the dye is incorporated in the culture medium; a zone of growth inhibition 4 mm. or more in diameter is taken to indicate sensitivity to the dye. The fermentation of a number of sugars, inositol, maltose, mannose, rhamnose, and trehalose, also has differential value. The physiological differentiation of Brucella species has been studied intensively8, 43, 44 and certain of the differential reactions are summarized in the accompanying table. Investigation of metabolic patterns among the Brucella species, such as the metabolism of amino acids, carbohydrates and Krebs cycle intermediates in respirometers, has shown a correlation of such patterns with species which sets

[†]On primary isolation.

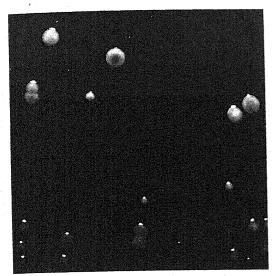

Figure 126. Colonial morphology of Brucella melitensis on liver infusion agar. The slight granularity is accentuated here, and the colonies are smooth, flattened, and slightly brownish in color. × 4.

Br. suis sharply apart-but also serves to characterize Br. melitensis and Br. abortus.36,37 A phage isolated by Russian workers is effective against Br. abortus but not the other two species.7, 10, 30 Phage sensitivity has been found, too, to correlate with oxidative metabolic patterns.35

The status of these physiologically differentiable types, reinforced by correlated differences in antigenic character (see below), as species of the genus Brucella, and their stability, appears to be established.63 The precise status is probably not of importance since Brucella species, like other species of microorganisms, are no more than form species, and the significant element is a generally accepted nomenclature.

The Brucella show the usual susceptibility to heat and disinfectants. A point of some practical importance is the rapid death of these bacteria at pasteurizing temperatures; both Br. abortus and Br. suis are killed in three minutes at 143° to 145° F. They persist in soil, water, and dust for one to two months but disappear within 10 days in milk, presumably in part as a consequence of the presence of acids formed by other bacteria. In this connection it is of interest that these bacteria are able to survive two hours or more in milk mixed with gastric juice.

Antigenic structure. Each of the three Brucella species contains two heat-stable antigens, designated as A and M. Br. melitensis contains a relatively large amount

Phanetic of a trailery bear

of M and a small amount of A, while both Br. abortus and Br. suis contain large amounts of A and small amounts of M. The ratio of A to M is said to be about 20:1 in the case of Br. abortus and 1:20 in the case of Br. melitensis. It is possible, then, to differentiate Br. melitensis from Br. abortus and Br. suis by serological methods, i.e., agglutination, but Br. abortus and Br. suis cannot be differentiated from one another in this way. Application of the gel-diffusion technique has shown a precipitating antigen in Br. melitensis which is seemingly not present in Br. abortus;46 This is perhaps the M antigen. In practice monospecific serums, i.e., serums adsorbed to remove the small amount of antibody common to the other immunological type, should be used. Immunoelectrophoretic analysis of sonic lysates of Br. abortus has shown that more antigens are present, at least

nine precipitable components.23

Toxin. No exotoxin is formed by these bacteria, but the cell substance of Brucella is toxic and the toxin has been found to be a component of the cell wall.14,31 A toxic antigen, prepared by tryptic digestion of dried cells followed by trichloracetic acid extraction and alcohol precipitation,42 appears to be a glucolipidpolypeptide complex. Further study, especially by Miles and his co-workers, has shown that the toxicity may be prepared as a highly purified material aminopolyhydroxy antigen, designated with a mouse LD₅₀ of 0.1 to 0.2 mg., and is hydrolyzed by dilute acid to phospholipid, formyl amine, and free amine, the last representing an amino sugar converted to a nonreducing anhydride during hydrolysis.38,39 The endotoxin appears to be substantially the same, in both nature and amount, in virulent and avirulent smooth strains. While it is considered probable that it contributes to the pathogenesis of the disease⁶⁰ and is thus a component of virulence, virulent strains appear to be able to multiply intracellularly, while the rough avirulent strains do not.6, 15, 16, 24 The nature of virulence is not yet clear. 49, 68

Variation. The Brucella species dissociate relatively easily to give rise to the rough form. The environmental factors affecting the dissociative process have been studied in detail by Braun. The $S \rightarrow R$ transformation is accompanied by a change to a rough colonial type, a loss of virulence, and alteration in immunological specificity. A point of particular interest is the relationship ingle-out-file and the part of the file for

550

of alanine to the $S \rightarrow R$ dissociation; that produced by the S form accumulates in the culture to toxic concentrations, and the S form is replaced by the alanine-resistant R form. Other environmental factors, including oxygen tension, contribute also. ^{2, 55} The antigenic alteration begins to take place before morphological changes are apparent and has been a source of considerable difficulty in the serological typing of these bacteria; the altered immunological types have been termed paramelitensis or para-abortus strains. It is, therefore, essential to use only smooth cultures in the serological differentiation of these bacteria.

A number of tests have been devised for the detection of antigenic variants. The rough forms are, of course, spontaneously agglutinated in saline. Slightly rough strains may be detected by their agglutination upon boiling in saline for two hours (thermoagglutination test) or by slide agglutination with acriflavine. The smooth colonies may be differentiated morphologically by culture on glucose-glycerol agar for 96 hours, flooding the plate with 1:2000 aqueous crystal violet, and examining after 15 seconds by oblique transmitted light; the smooth colonies are a light blue-green, while the nonsmooth vary from red to blue-red or violetred.67

Pathogenicity for lower animals. 28, 50 Brucellosis is primarily a disease of domestic animals and is only secondarily communicated to man; the chief animal reservoirs are goats, cattle, and swine. It is of some interest that host specialization of the parasites has taken place, giving rise to the three species or, as some prefer to regard them, varieties of Brucella.

Goats.64 Goats may be artificially infected with Br. melitensis by almost any route, and it is probable that under natural conditions the vaginal discharge at the time of aborting and shortly thereafter plays an important part in the dissemination of the infection. Agglutinins appear in the blood of artificially inoculated pregnant goats by the third or fourth day, and the titer rises rapidly to perhaps 1:1000 within 48 hours and reaches a peak of 1:2000 or thereabouts by the twelfth day of infection. Just before the peak in agglutinin titer, bacteremia is initiated which persists for perhaps one month. This acute generalized infection becomes localized during the second month after the termination of the pregnancy during which the animal was infected. In most cases the bacteria do not persist in the udder and

uterus after the fifth month following termination of pregnancy. A second pregnancy does not, as a rule, cause an exacerbation of the disease, but in some cases the infection may remain localized in the area of the genital tract for several years.

The most obvious clinical symptom of infection is abortion, but it does not occur consistently. Pyrexia is apparent within 48 hours of the generalized infection, and there is slight diarrhea. The placenta is not retained, but a copious vaginal discharge is frequently observed for two or three weeks after kidding. In lactating goats the milk may be physically altered and appear in extreme cases as a clear fluid containing suspended clots.

Immature goats are highly resistant to the infection, and kids born of infected dams may not be infected and commonly do'not become so in spite of the ingestion of enormous numbers of Brucella in the milk. Nonpregnant mature goats are also resistant to infection and respond to artificial inoculation with only a low and transient agglutinin titer in the blood serum.

Brucellosis in sheep is similar to that in goats.

Cattle. Brucellosis in cattle is most commonly an infection with Br. abortus, although both Br. melitensis and Br. suis have also been found. The microorganism may gain entrance by a variety of routes, including direct inoculation into the vagina, by way of the conjuctiva, through the unbroken skin, or via the alimentary tract. The primary symptom of the disease is abortion of the fetus by pregnant cattle. The time elapsing between initial infection and abortion varies from three weeks to four months, and the period of gestation at which abortion may take place varies from two to nine months. Cattle do not abort, however, unless infected during pregnancy and even then not all abortperhaps 30 per cent-or the cattle may become sterile. Subsequent pregnancies may proceed normally in spite of persistence of the infection; second abortions are not common, and third abortions are rare.

The bacilli may be found in the blood in perhaps 10 per cent of the cases and are very likely consistently present during the acute infection. Early in the infection the bacteria are found in the lymph glands about the head and intestines, by the end of the first month they are found all through the body, and by the end of the third month they have localized in the mammary glands and

are found only in the udder. The invasion of the udder results in an acute or chronic inflammation with lesions in the alveoli and interalveolar connective tissue and, when the lymph glands are involved, a chronic lymphadenitis. Chronic infection of the udder may persist indefinitely without significant differences in the quality of the milk, and bacilli may be excreted over a long period, perhaps for life. The uterus, on the other hand, frees itself of the bacteria relatively soon, and the vaginal discharges do not contain the bacilli for an extended period.

Animals infected during pregnancy show an agglutinin titer ranging from 1:200 to 1:1000 which falls slowly over a period of six months or so. Cattle that continue to excrete bacilli in the milk generally show persistent agglutinin titers of 1:200 or more, although a titer of 1:50 has diagnostic significance. Agglutinins are also present in the milk and may be demonstrated in the whey after clotting with rennin. Infected animals become sensitized to the bacillary substance, and a skin reaction may be elicited by the intradermal injection of a preparation of Brucella protein designated as abortin or brucellergen. As in the case of the young goats, calves are relatively resistant to the infection.

Swine.29 Brucellosis of swine seems always to be due to infection with Br. suis. though these animals may be artificially infected with Br. abortus. In contrast with cattle, the males are commonly infected. and abortion in infected females is less frequent than in cows; about 50 per cent of swine abortions are due to unknown causes, not brucellosis. The clinical symptoms may be mild or lacking, and in a number of instances there has been no outward evidence of the disease in an infected herd, but the proportion of swine infected is as high as 20 per cent in some localities. Under natural conditions infection may take place via the alimentary tract. The infected boar, a testicular infection, is undoubtedly a significant element in the dissemination of the infection. The bacilli are eliminated with aborted fetuses and vaginal discharge, urine, semen, and milk.

Other animals. A number of other animals have been found to be naturally infected with Brucella. There is some evidence that the disease of horses known as fistula of the withers or poll evil is a Brucella infection; both Br. abortus and Br. suis have been isolated from cases of the disease.

Stone⁶⁴ found that 9.5 per cent of horses tested in New York City gave positive serological reactions. Brucella infections of fowl have been reported; in one instance Br. suis was isolated from several naturally infected birds, but the disease is probably not common. Dogs may also be infected naturally; Br. suis and Br. abortus have been isolated. Wild rats may be artificially infected, and Br. abortus has been isolated from a naturally infected rat. Natural infection of rabbits with Br. melitensis has also been reported. Of the usual laboratory animals, guinea pigs are readily infected and are most often used for experimental purposes. A fatal infection is produced in the mouse, using the mucin technique,9 and the embryonated egg is readily infected. 18, 32

Pathogenicity for man. 21, 41, 56 Man is susceptible to infection with these three species of Brucella, but infections with Br. melitensis and Br. suis are usually more severe than those with Br. abortus. The incubation period of undulant fever in man is highly variable and relatively long; it may range from one week to not less than four months. The case fatality is low-2 to 3 per cent. It may have varied clinical manifestations, and five types are recognized: (1) the intermittent type with shifting articular rheumatism, weakness, night sweats, and a temperature near normal in the morning but rising to 101° to 104° F. in the evening, in which the patient remains in bed in the latter part of the day; (2) the ambulatory type with much the same symptoms but to a mild degree; (3) the undulant type, generally melitensis infections, characterized by step-like increases in the temperature from day to day to a maximum and, after a time, gradual decrease in temperature and possibly successive repetitions of this sequence of events; (4) the malignant type, almost always melitensis infections, in which the temperature is high and sustained with extreme hyperpyrexia before death; and (5) an atypical chronic type which may take the form of muscular stiffness, gastric disturbances, and various neurological symptoms. In general, undulant fever is a disease of relatively long duration, one to four months, and relapses during convalescence are not infrequent. In a chronic form undulant fever may be difficult to diagnose; or it may be effectively subclinical as indicated by the isolation of Brucella from apparently healthy persons. A group of laboratory infections provided a unique opportunity for the study

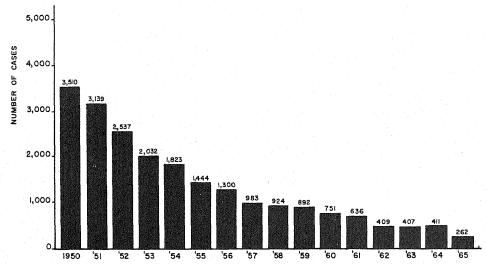

Figure 127. Cases of human brucellosis reported in the United States, 1950–1965. (Morbidity and Mortality Weekly Report, Annual Supplement, Vol. 14, No. 53. Communicable Disease Center, Public Health Service, U. S. Department of Health, Education, and Welfare.)

of the evolution of the disease in man;⁶⁵ an interesting feature was the association of neurosis and emotional disturbance with the prolonged convalescence.

Brucellosis in man is a generalized infection as a rule, while in lower animals it is a localized infection, particularly in cattle. The bacilli may be isolated from the blood stream in man,17 and the development of agglutinins is a diagnostic aid. Man also becomes sensitized to the cell substance of the bacteria, a hypersensitivity that is sometimes manifested as skin eruptions which may be macular or resemble the rose spots of typhoid fever. Localization may occur, however, and meningitis and meningo-encephalitis are probably not so rare as has been supposed, while in some instances orchitis, cholecystitis, endocarditis, and other local manifestations have been reported. Pulmonary lesions with infiltration of the hilar glands or lung tissue proper are occasionally observed. Pulmonary infection has led many investigators to suspect infection by inhalation, and Elberg and Henderson¹² have shown that the guinea pig may be experimentally infected by an intake of about 36 microorganisms inhaled as an aerosol. Brucella infection may be associated with abortion and mastitis in the human female in rare instances. As indicated above, the endotoxin appears to contribute in large part to the pathogenesis of the disease, both directly and indirectly as a hypersensitivity.57

Epidemiology. 22, 47 Brucellosis in is probably always acquired from infected domestic animals; man-to-man transmission is a possibility but rarely, if ever, occurs. The commonest modes of infection in the United States are the use of raw milk from infected cattle, and direct contact with the flesh of infected animals, both cattle and swine. As indicated above, animals may be readily infected via the alimentary tract, and it is not unreasonable to suppose that man is infected in this way also. The discharge of Br. abortus in the milk of infected cattle, then, provides the opportunity for infection when the milk is ingested in the raw state, and in many instances undulant fever is aguired in this way. Br. abortus has been found in certified milk in a number of localities. The pasteurization of milk, of course, provides adequate protection from this source of infection.

The penetration of the unbroken skin by Brucella has been pointed out earlier. Man may be infected by the handling of the tissues of diseased animals or by close contact with other infectious material; presumably the bacilli enter through minute abrasions in the skin or possibly through the intact skin. Employees of slaughterhouses, veterinarians, sausage-makers, and butchers are, of course, particularly exposed to infection by this means, and the incidence of brucellosis in this group is disproportionately high, with a tendency to be an occupational disease. It is probable that most infections with

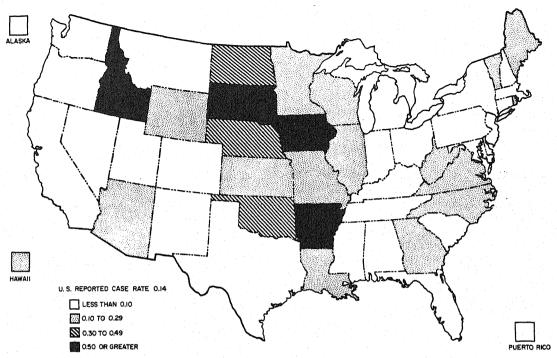

Figure 128. Geographical distribution of reported cases of human brucellosis per 100,000 in the United States in 1965. (Mordibity and Mortality Weekly Report, Annual Supplement, Vol. 14, No. 53. Communicable Disease Center, Public Health Serivce, U. S. Department of Health, Education, and Welfare.)

Br. suis are aquired in this manner, although in some instances cattle are infected with this species and man aquires a suis infection via raw cow's milk. The epidemiology differs somewhat from one locality to another. In Iowa the incidence is highest among packing house workers and male farm workers, and in Indiana direct contact appears to be most important. In Utah, however, infected dairy products are the most important source of infection. In general, brucellosis is more common in males than females, in a ratio of about 4:1.

Laboratory infections with Brucella are very common, and even the most skilled workers have acquired undulant fever through working with these bacteria. Meyer and Eddie³⁴ reviewed 74 cases up to 1940, of which 44 occurred in competent bacteriologists. These infections are, in all probability, a consequence of handling infectious material and penetration of the skin by the microorganisms.

Undulant fever may also be acquired by drinking raw goat's milk, but infections with Br. melitensis from these animals are thought to be relatively infrequent in the United States. A number of cases have been found in North Carolina, Kansas, and Texas, and

it is known to occur in the Southwest in general where goat's milk is consumed. In Arizona the incidence of *Br. melitensis* infection is directly related to the goat population and has declined coincident with a reduction in the numbers of goats, while *Br. abortus* infection has remained high.

It has been shown experimentally that brucellosis may be transmitted by mosquitoes and biting flies, but at present there is no indication that this mode of transmission is of any significance in nature. Water is apparently not a vehicle of transmission; the single waterborne outbreak that has been reported was in the nature of a laboratory accident.⁴⁰

The prevalence of human brucellosis is not known with any degree of precision. The reported incidence of brucellosis reached a peak in 1947 with 6321 cases, declined to 3139 in 1951, 1300 in 1956, to 636 in 1961, and to 240 in 1966; the number of reported cases tends to reflect general interest, or laxity in reporting. The midwestern states, Iowa, Minnesota, and Wisconsin, contributed 25 per cent of all cases in the 10-year period 1942 to 1951 and 50 per cent of cases reported in 1951. The disease is found in rural areas for the most part, and the inci-

roving house to somewhater with

554 **BRUCELLA**

dence in urban areas is very low. The incidence is high in the midwestern states and, in geographical distribution, tends to parallel the extent of the hog-raising industry. The incidence of brucellosis in cattle is relatively high, about 4 per cent of adult females, and more or less uniform throughout the country. Swine brucellosis is not so common; about 3 per cent of hogs show significant agglutinin titers. The estimated annual loss to the livestock industry is about 100 million dollars.

Bacteriological diagnosis. 26, 53 The laboratory diagnosis of brucellosis involves the demonstration of the causative microorganism and of specific antibodies. When the bacterium can be isolated and identified the diagnosis is solidly established, but the presence of antibodies indicates only an immune response to what may have been a past rather than present infection and is, therefore, only suggestive.

Brucella is more often found in the blood stream in man, particularly in the pyrexial period, but cannot always be isolated. Blood or blood clot is added to tryptose broth in 2 to 5 ml. amounts and incubated in an atmosphere containing 25 per cent CO₂. The enrichment culture should be subcultured at four-day intervals and, if subcultures are negative, carried for a period of not less than three weeks. For subculture, agar plates of liver infusion or tryptose agar should be inoculated. The bacteria may be identified by agglutination with antiserum; differentiation between Br. melitensis and Br. abortus-Br. suis may be made by agglutination with type-specimen antiserum, and the culture tested for H₂S production and growth in the presence of thionine and basic fuchsin.

A presumptive diagnosis made on clinical grounds may be partially, but by no means absolutely, confirmed by an agglutinin titer of 1:320 or higher or by a rising antibody titer during the course of the disease. Unfortunately, agglutinin titers differ from one laboratory to another, and there is pressing need for the use of a standard agglutinating antigen and agglutination procedure. 62 A rapid test has been devised by Ruiz Castaneda51 which does not require laboratory facilities.

Blocking antibody occurs which interferes in the direct agglutinin titration. There has been considerable interest in the diagnostic utility of incomplete, or blocking, antibody titration by the antiglobulin method.20,66,69 The significance of such titers

is somewhat uncertain; it is believed that incomplete antibody tends to be formed relatively late in the disease, and possibly may be taken to indicate the presence of active infection, e.g., continued antigenic stimulus.

Interpretation of the agglutinin response is also complicated in some instances in which the individual has received cholera vaccine, for Brucella and the cholera vibrio contain common antigens. The allergic response to Brucella cell substance, demonstrable as a skin reaction of the delayed type, is now regarded as quite unreliable for diagnostic purposes.

The agglutination test is widely used in the diagnosis of brucellosis in cattle. Agglutinins are present in milk as well as serum, and in the latter case a "ring test" (the Abortus Bang Ringprobe, or ABR test) is commonly used. It consists of mixing one drop of hematoxylin-stained bacteria with 1 ml. of milk, incubating for one hour at 37°C., and reading; the agglutinated bacteria are carried to the surface with fat globules to

form a colored ring.

Chemotherapy. 13, 52, 58 Chemotherapy of brucellosis has been disappointing, and the disease responds only irregularly and temporarily to administration of sulfonamides and the antibiotics. There is some evidence that combined therapy, as with sulfadiazine plus antibiotics or a combination of tetracyclines and streptomycin, may terminate acute clinical episodes, but relapses occur, ranging from 20 to 50 per cent. Of the antibiotics, the tetracyclines are considered to be the most effective.

Immunity.²⁷ The resistance of calves and nonpregnant cows to clinically apparent brucellosis is clearly an expression of natural immunity, though the older animals respond to the microorganism with the production of antibodies and the development of an increased resistance to subsequent infection. Man likewise appears to have a high degree of natural resistance to the infection, and it is probable that there are many more infections than clinical cases of brucellosis. In the series studied by Huddleson and Munger in which exposure to infection was known, only about half the individuals showing evidence of infection by an immune response had clinically apparent disease.

In man the immune response is evidenced by the appearance of agglutinins, opsonins, bactericidal antibody,4 and hypersensitivity to preparations (brucellergen) of the cell

substance of the bacteria. It is not clear. however, that this response is associated with an increased resistance, i.e., effective immunity, to the infection. The available evidence suggests than an effective immunity is primarily a cellular immunity. 25 Consistent with this, the therapeutic use of antiserums in human brucellosis has given disappointing results.

Vaccines. 48 The possibility of producing an effective prophylactic immunity, not only in man but also in animals, is of continued interest. Vaccines consisting of killed suspensions of the bacteria induce a serum antibody response, demonstrable as agglutinins. etc., but do not produce an immunity to the disease.

An avirulent variant of Br. abortus, strain BA 19, has been studied extensively as a possible immunizing agent. It differs from virulent strains of Br. abortus in that it does not require carbon dioxide, is relatively avirulent for the guinea pig, and is inhibited by thionine blue. Used in calves, it does not prevent infection but modifies the disease as indicated by a sharply reduced rate of abortion and shedding of the virulent bacteria. It is not completely avirulent for man, and a number of accidental infections have been reported.^{54, 61} In man it does not produce chronic disease, but induces a degree of hypersensitivity such that subsequent contact with Brucella antigen gives severe reactions.⁵⁹ It has been administered to man in Russia, reportedly to as many as 11 million persons, and is said to reduce the incidence of brucellosis as much as 10-fold.45

An avirulent mutant of Br. melitensis, designated Rev 1, has been studied by Elberg and his co-workers. It behaves in the guinea pig as if it were a virulent organism until the infection becomes established; it appears to have little pathogenicity as an intracellular parasite, and the lesions disappear,33 Similar results have been obtained with monkeys, using only a few hundred cells as inoculum, to produce an immunity effective against subsequent challenge with virulent bacilli.11 It appears highly promising, but as yet is in an experimental stage.

BRUCELLA BRONCHISEPTICA

This microorganism is very similar to Br. abortus but is motile and highly aerobic. It does not produce hydrogen sulfide. It is

immunologically related to Br. melitensis and Br. abortus but can be separated from them by agglutinin-absorption tests. It also resembles Hemophilus pertussis both culturally and immunologically. Originally isolated from dogs ill with distemper, it is not now generally believed to stand in any causal relation to that disease. It is, however, frequently found as the cause of bronchopneumonia in guinea pigs and other rodents.

PASTEURELLA AND ACTINOBACILLUS

Hemorrhagic Septicemia; Plague; Tularemia; Glanders; Actinobacillosis

Pasteurella

The group of bacteria making up the genus Pasteurella consists of biochemically inactive, nonmotile, gram-negative bacilli which often show bipolar staining. The group is relatively homogeneous, with the exception of the tularemia bacillus, which is set apart by its fastidious nutritive requirements and certain other characteristics, and is differentiable by physiological properties as shown in the accompanying table. These bacteria are primarily pathogens of lower animals.¹¹ The etiological agent of fowl cholera was among the first of them to be described, and was the bacterium used by Pasteur in his early studies on immunity.

Pasteurella multocida (Pasteurella septica). The group of animal diseases loosely designated as hemorrhagic septicemias, and characterized by large and small hemorrhagic areas found in the subcutaneous tissues, serous membranes, muscles, lymph glands, and throughout the internal organs, are considered to be caused by a single species, Past. multocida or Past. septica. Strains may differ widely in virulence and to a certain degree in host specificity, and for many years were given corresponding names, viz., Past. aviseptica or Past. avicida, the cause of fowl cholera and pathogenic for mammals as well; Past. muriseptica or Past. muricida, pathogenic for rodents but not fowl; Past. leptiseptica or Past. cuniculicida, associated with contagious nasal catarrh, or "snuffles," of rabbits; Past. suiseptica or Past. suilla, the bacillus of swine

plague which is pathogenic for both mammals and birds; and *Past. boviseptica* or *Past. bollingeri*, found in domestic animals.

These bacteria may be grown on the conventional nutrient agar mediums, and show no hemolysis on blood agar although the colonies may become darkened. They occur as distinct colonial types, smooth, mucoid and rough. The smooth forms are iridescent when examined by oblique transmitted light, and Elberg and Ho37 described three types, the green or golden being the most virulent, and the red and blue of decreasing virulence; the noniridescent mucoid type is avirulent. They are separable into four groups on the basis of arabinose-xylosedulcitol fermentations which approximate, but do not necessarily coincide with, immunological type; characterization as types is immunological rather than biochemical. Roberts differentiated four serotypes, designated I, II, III, and IV, and this was carried further by Carter,20 who designated the types B, A, C, and D corresponding respectively to Roberts' types. The immunological specificity is attributable to specific polysaccharide, and is demonstrable by precipitin, capsular swelling, and passive hemagglutination reactions; effective immunity is type-specific. A lipopolysaccharide has been isolated109 which is both immunogenic and toxic. There is an association between colonial morphology and antigenic characteristics;21 specificity is a property of the smooth form, and mucoid strains are often not typable.

^{*}Sparse, disappearing after two to three days' incubation.

†Acid, no gas.

The pathogenicity of Past. multocida is sometimes considered to be open to question because of the relatively common occurrence of the bacteria in normal animals. It appears, however, that strains isolated at random are of widely varying virulence. and those found in normal animals are commonly the avirulent mucoid form. Virulence appears to be associated with serotype to the extent that type B (I), which is largely confined to Southeast Asia, is the etiological agent of classic hemorrhagic septicemia occurring in cattle and other domestic animals. The other types are associated with fowl cholera and bovine and swine pneumonias in this country and in Europe.

Human infections are reported from time to time⁴⁷ and, curiously, have been found more often in Oregon in recent years than elsewhere in the world.⁵⁴ The A and D

serotypes tend to predominate, suggesting domestic animals as sources of human infection.²²

Pasteurella hemolytica. This bacterium is closely similar to *Past. multocida*, but is differentiable by its formation of indole and failure to ferment maltose, and is immunologically distinct. It appears to be the cause, or a common cause, of shipping fever of cattle,²³ but is apparently able to produce disease under natural conditions only when the resistance of the animals is reduced by stress. It is also a cause of ovine mastitis, and has been called *Past. mastitidis*.

PASTEURELLA PESTIS — THE PLAGUE BACILLUS^{44, 51, 78, 103, 104}

Plague is an ancient disease, originating in central Asia and/or central Africa. Whether the Biblical plague of the Philistines in 1320 B.C. was plague of Pasteurella etiology as contended by some, or an epidemic of dysentery and piles (the last is difficult to believe) as asserted by others, is uncertain, but the great pandemic during the reign of the Emperor Justinian in 542 A.D. was certainly plague.

Plague prevailed extensively throughout Europe during the Middle Ages. It has been estimated that 25,000,000 persons, or one-quarter of all inhabitants of Europe, perished in the "great mortality" or "Black Death" of the fourteenth century (1348-49). Few diseases have left so deep a mark on general literature. Boccaccio's *Decameron* contains one of the most vivid descriptions of the plague ever written, and Defoe's

fictitious* Journal of the Plague Year provides a realistic picture of the devastation of London in 1665 by an outbreak of Black Death in which 70,000 persons perished.

For reasons that may be only partly conjectured, plague has had irregular periods of quiescence and recrudescence. Western Europe has been practically free from the plague since the middle of the eighteenth century, and the disease began its first great extension in modern times with its appearance in 1893 in Hongkong and in 1896 in Bombay. Plague caused great loss of life in British India; official statistics show that in the period from 1896 to 1918 more than 10,000,000 deaths were due to this disease. In October, 1899, a case was recorded at Santos, Brazil; this is thought to be the first occurrence of the plague in the Western Hemisphere. Plague first appeared in the United States in San Francisco in 1900: it is assumed that it was introduced by infected rats from the Orient. The infection apparently spread to ground squirrels and other wild rodents in the western part of the country.

Plague continues to decline, but this is considered to represent a continuation of its decline from its most recent epidemic prevalence, rather than a prelude to its extinction. In fact, the infection is now more firmly established in endemic foci than at

any time in the past, and it may be a disease of the future as well as of the past.³

The plague bacillus, *Past. pestis*, was discovered almost simultaneously by Yersin and by Kitasato in 1894.

Morphology and staining. The plague bacillus is a short, plump, ovoid rod 0.3 to 1.25 μ in length. In the body fluids the bacillis may occur in pairs, but long chains are rare, and, in general, there is no characteristic arrangement. The bacilli are nonmotile and a surface slime layer, polypeptide in nature, is present. The presence of this material, as an envelope or capsule, is associated with resistance of the bacilli to phagocytosis.⁵⁹ Involution forms are common, especially in older cultures, and coccus shapes, large rods, and gigantic swollen forms may be observed. The tendency of the plague bacillus to aberrant morphology is accentuated by cultivation on mediums containing 3 to 4 per cent sodium chloride; the appearance of involution forms in 24hour cultures on salt-containing mediums has been regarded by some as a characteristic of differential value.

Colonies on nutrient agar or gelatin have a delicate, drop-like appearance, with a round, granular center and a thin, granular, uneven margin. On blood or other hemincontaining mediums the colonies are dark brown in color, the pigmentation being derived from absorption of hemin from the substrate.⁵⁷

The plague bacillus is uniformly gram-

^{*}Defoe was only four years old in the year of the great plague.

negative and shows a marked tendency toward polar staining, i.e., there are heavily stained areas at the ends of the cell separated by a lightly stained area in the center. For good bipolar staining the smear should be air-dried and fixed in alcohol. The usual aniline dyes, such as methylene blue, are satisfactory. The plague bacillus is best demonstrated in tissue sections by a polychrome stain.

Physiology. Past. pestis is not nutritionally fastidious, and growth occurs on all the ordinary culture mediums, although in pentone water it is very poor. Unselected strains require amino acids as sources of nitrogen, and certain amino acids appear to be essential for some strains;50, 112 apparently bacterial vitamins are not required. Casein hydrolysate has been widely used as a base for liquid mediums in the production of vaccine at the Haffkine Institute¹¹⁸ for many years, and more recently in studies of toxin and other antigenic products, but hematin, blood, or possibly reducing agents are required for growth on the surface of a solid medium. Unlike the case with most of the bacteria pathogenic for man, a temperature of 25° to 30° C. is more favorable than one of 37° C., and the limiting temperatures for growth are -2° C. and 45° C. In any case, the colonies on solid mediums grow slowly and never attain a large size. The plague bacillus is aerobic and facultatively anaerobic.

Sugar fermentations are variable, including that of glycerol, and a small amount of acid but no gas is produced. Neither coagulated serum nor gelatin is liquefied, and indol is not produced. Nitrates may be reduced to nitrites, and a small amount of hydrogen sulfide is formed. On potato and in milk multiplication is slow and scanty; milk is rendered slightly acid but is not curdled.

Devignat has distinguished three physiological varieties of the plague bacillus. 31, 102 Variety I, Past. pestis orientalis, does not ferment glycerol but reduces nitrate; variety II, Past. pestis antiqua, ferments glycerol and reduces nitrate; and variety III, Past. pestis mediavalis, ferments glycerol and does not reduce nitrate. The last ferments melibiose while the first two do not, to provide an additional differential character. 93

The primary foci of infection of variety I are in India, Burma, and south China;

variety I was the agent of oriental plague which caused the 1894 epidemic and it is also responsible for sylvatic or wild rodent plague in the western United States. Variety II, probably the oldest, came from Transbaikalia, Mongolia, and Manchuria in central Asia, moved west with the Aryan invasions, and followed the valley of the Nile into central Africa, leaving foci that persist to the present time. It also moved back toward the Mediterranean in the sixth century and is believed to have been responsible for the Justinian plague that spread through the Roman Empire. It has since disappeared from Europe and has remained isolated in Africa. Variety III, possibly arising by a slow transformation of variety II, spread from the Caspian Sea throughout the whole of Europe, causing the Black Death, and established itself in endemic foci.

The plague bacillus does not exhibit any marked resistance to deleterious influences. Exposure to drying, particularly at the higher summer temperatures, kills it within a short time. The bacillus is quite sensitive to the action of sunlight and chemical disinfectants; it is killed, for example, by 0.5 per cent phenol in 10 to 15 minutes and by heating to 55° C. in about the same time. Cultures kept in the refrigerator, however, remain viable over long periods. In general, *Past. pestis* does not survive long outside the animal body and disappears rapidly from soil, water, and buried cadavers.

Toxin. The toxicity of the plague bacillus appears to be intermediate between endotoxin and exotoxin. The toxicity is not associated with somatic glucolipid-poly-

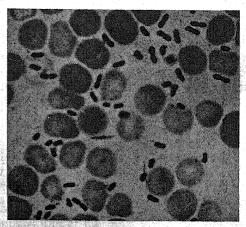

Figure 131. The plague bacillus in the blood of an infected mouse, \times 2000. (Douglas and Wheeler.)

peptide complexes as in the case of the enteric bacilli, but, while it appears to be protein in nature, it does not diffuse freely into the surrounding medium like the diphtheria, tetanus, and botulinus toxins. Toxic extracts have been prepared by freezing and thawing of suspensions, followed by centrifugation and filtration, and by autolysis and separation of the toxic supernatant. Toxicity in soluble form may also be prepared by phage or bile salt lysis of the bacilli.

On local inoculation the toxin produces edema, often followed by necrosis, and the general effect appears to be largely on the peripheral vascular system and liver to produce shock which is irreversible when a lethal dose is given. It appears to have no selective action on the heart or central nervous system. The pathology in toxin-sensitive animals—mice and rats—is closely similar to that produced in infection, but this similarity is not observed in other animals.¹¹⁴

This murine toxicity has been prepared in highly purified, antigenically homogeneous form by salting out procedures and electrophoretic fractionation of extracts of acetone-dried bacilli.1 This material contains 18 amino acids, but no polysaccharide or phosphorus, has a molecular weight of about 74,000, and a mouse LD₅₀ of 0.1 μ g. or less. It splits NAD, inhibiting NADdependent reactions such as the oxidation of keto acids² and inhibits the respiration of rat and mouse heart mitochondria, but not that of mitochondria from toxin-resistant animals such as the rabbit.62 The murine toxin has been separated by electrophoresis into two toxic protein fractions differentiable from one another.⁹⁴ There is evidence²⁷ which suggests that the murine toxins do not account for all the toxicity of the plague bacillus.

Virulence.17, 120 The murine toxin is found in both virulent and avirulent strains of the plague bacillus, and interest in matters such as variation and antigenic structure has centered largely around the question of virulence. The usual S-R dissociation occurs, but the colonial morphology, and associated properties, is not related to virulence since both S and R forms may be either virulent or avirulent.36 Similarly, the plague bacillus is antigenically homogeneous in that serotypes, in the conventional sense, do not occur, but the antigenic structure is complex as shown by sensitive techniques such as gel-diffusion.25 The murine toxin is one antigenic component, and the polysaccharide-protein envelope substance. or antigen, designated Fraction 1, is another which is associated with virulence, but either or both may be present in virulent strains.

More recently the various factors associated with virulence have been clarified. The presence of Fraction 1 is associated with the resistance of the bacilli of phagocytosis, but doubt as to its indispensability to virulence is raised by the occurrence of virulent strains lacking, or containing only very small amounts of, Fraction 1; such strains have been isolated in the laboratory as mutants and in the naturally occurring fatal infection in man.¹²⁴

Two antigens, designated V and W and demonstrable by gel-diffusion, have been described, 18.75 which appear to be invariably

[‡]Strains lacking only the ability to form pigment are fully virulent when Fe⁺⁺ is inoculated simultaneously with the challenge dose.

associated with virulence; they do not occur separately, but may vary in relative amount, and are thought to relate to the resistance of the bacilli to phagocytosis.

Certain nutritional requirements have also been associated with virulence, or avirulence, one is a temperature-dependent requirement for calcium⁵⁰ of virulent strains, and the others are nutritional deficiencies occurring in avirulent mutants. Of the latter, one relates to pigmentation of colonies on hemin-containing mediums noted earlier; nonpigmented mutants are avirulent unless the animal is inoculated concurrently with hemin or ferrous iron.58 There appears to be a relation between ferrous iron and pesticin I, a bactericin-like substance produced by wild-type strains and associated with coagulase and fibrinolytic activity, in the virulence complex.13 The other is a purine deficiency mutant for which virulence is similarly demonstrable when the deficiency is supplied at the time of inoculation.16 Such restoration of virulence to deficient mutants is presumably a matter of supplying nutritive requirements not satisfied by the tissues of the host, i.e., an effect on bacterial growth in vivo. Maintenance of virulence in culture is markedly influenced by environmental factors.97

In summary, a virulent strain of Past.

pestis may be defined as a toxigenic, encapsulated strain containing the VW antigen complex, forming pigmented colonies on hemin-containing mediums, and able to survive and grow in macrophages.²⁴

Pathogenicity for man. Plague in man appears most commonly in two forms, the bubonic or glandular plague and plague pneumonia. In the bubonic type the symptom complex is characteristic, and diagnosis on clinical grounds is relatively simple. From the buboes, which may be either primary or secondary, bacilli may pass over into the blood; in fatal cases the bacteria often multiply in the blood extensively. The case fatality is 60 to 90 per cent. Primary plague septicemia can also probably occur. There are sometimes subcutaneous hemorrhages. During the plague epidemics in the Middle Ages such hemorrhages seem to have been more frequent than at present, and the dark spots to which they give rise were the origin of the popular name. "Black Death."

Plague pneumonia⁸⁹ occurs secondary to the glandular infection and may be transmitted to give rise to primary plague pneumonia. Pneumonic plague is usually fatal. In this variety the sputum may contain enormous numbers of plague bacilli, and the infection is spread from man to man by

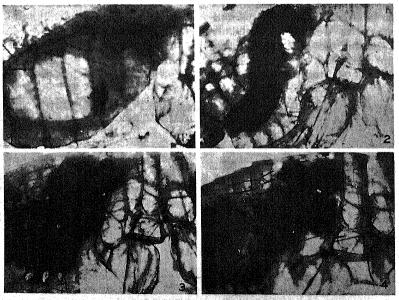

Figure 132. Plague bacilli in the infected flea; sections stained with methylene blue. The bacilli appear as dark stained masses. I, flea on the ninth day after infection. 2, eighteenth day after infection; note the stomach and proventriculus packed with bacilli. 3, twenty-second day after infection; note the large mass of bacilli and the swollen proventriculus. 4, twenty-third day after infection; the proventriculus is further enlarged. (Douglas and Wheeler.)

droplets. Because of this direct spread, pneumonic plague is by far the more dangerous type. The extensive outbreak of pneumonic plague in Manchuria in 1910 to 1912 is said to have caused approximately 60,000 deaths, the case fatality being practically 100 per cent. Both bubonic and pneumonic plague have been produced experimentally, giving in the monkey diseases which closely resemble the human infection. ^{53, 107, 119}

EPIDEMIOLOGY OF PLAGUE

A primary infection of the skin with the plague bacillus sometimes occurs (cutaneous plague) but does not seem to be common. Cases of mild plague, the so-called pestis minor, are met with in some epidemics, but it is probable that healthy persons do not carry plague bacilli for long, if at all. The occurrence of intestinal plague in man has never been clearly established.

Epidemiology. Plague is a disease of rodents which also occurs in man as sporadic cases and in epidemic form. The susceptible rodents fall into two groups: the domestic rodents, or rats, and various wild rodents. Of the former, the black house and ship rat, Rattus rattus, and the less susceptible gray sewer rat, R. norvegicus, are most commonly involved; the Egyptian rat, R. alexandrinus, may be infected also. Although both the feces and urine of infected rats may contain plague bacilli, and rats may be infected by feeding upon rats dead of the disease, the infection is most often transmitted by fleas. The Indian rat flea, Xenopsylla cheopsis, is a common, and perhaps the most effective, vector, but the rat flea of North America and Europe, Ceratophyllus fasciatus, may also transmit the disease. Plague bacilli are present in the blood during the acute disease, as many as 100 million per ml., and the flea is infected by feeding on the diseased rat.

When the plague bacilli are taken into the stomach of the flea they multiply, but do not spread to other parts of the body, and on microscopic examination large masses of bacilli may be seen in the infected flea. In some the bacilli multiply so rapidly that the bacterial mass mechanically obstructs the proventriculus so that little or no food may pass. In the effort to feed, plague bacilli are mixed with the drawn blood of the host, and regurgitated into the bite. The bacilli are also discharged in the feces, and infection may occur by contamination of the bite wound with fecal pellets.

A wide variety of wild rodents can be, and are, infected with plague, and this rodent disease, improperly referred to as sylvatic plague, constitutes the reservoir of infection. In the United States wild rodent plague was first observed in California in 1908, and has spread slowly eastward, reaching into Texas, Arizona, New Mexico, Oklahoma, and Kansas. Rodents such as prairie dogs, ground squirrels (Citellus), wood rats (Neotoma), and mice (both Microtus and Peromyscus) may be infected, 38, 65, 77 and there is evidence that rabbits may be involved in some areas.64 Various rodents are infected in other parts of the world:110 the sisel, Citellus pygmaeus, in the northwest Caspian area; various species of Meriones in Kurdistan; the Indian gerbil, Tatera indica, in India; the field rat, R. exulans, in Java; etc.

It is well known that plague exists in two kinds of endemic centers, temporary and permanent, and the status of the domestic rat as a reservoir of infection has been doubtful. Similarly, a postulated role of the rat flea in the dissemination of human epidemic plague has been subject to serious exception with the occurrence of epidemic plague in the absence of rats and their fleas. More recently the epidemiology of the disease has been considerably clarified. Extensive studies, beginning in Kurdistan, have made it clear (a) that the permanent reservoirs of infection are in relatively resistant wild rodents; (b) that foci of wild rodent plague tend to die out when the animals are susceptible to the disease; (c) that the domestic rat is no more than the "liaison rodent" between the wild rodent and man; and (d) that while infection is initially carried to man by ectoparasites of rodents, epidemic bubonic plague in man is transmitted largely from man to man by human ectoparasites, notably the human flea, Pulex irritans.

The epidemiology of plague falls into a pattern on the basis of the foregoing. For example, in Kurdistan four species of wild rodents constitute the reservoir of infection: Meriones libycus and M. persicus are highly resistant to plague, and M. tristrami and M. vinogradovi are extremely susceptible. The persistence of plague is a consequence of the balance among these species, and the sedentary habits of the resistant species whose burrows act as reservoirs of infected fleas. On occasion a human infection is acquired from this source, and this gives

rise to human plague in villages, which is transmitted by the human flea.8 When the villages are small and scattered, and communications slow, the epidemic is limited and dies out. Throughout this permanent epidemic area, including southeastern Russia, the infection persists in very many small permanent foci of infection where the various Meriones species are closely intermingled. In Java the field rat is resistant, and plague persists in permanent foci; the domestic rat is relatively rare in rural areas, too restricted in range to spread the infection and too susceptible to maintain it for any length of time.⁵ Consequently, plague in Java is typically sporadic, brief, and limited to villages. In the United States Microtus and Peromyscus are resistant to plague and for that reason are probably a more important reservoir of infection than the more susceptible ground squirrel.

In contrast, the focus of infection in Mesopotamia remains temporary, occurring in susceptible rather than resistant wild rodents, and tends to die out unless periodically reactivated by importation of infection.⁶ Similarly, in India the gerbil is somewhat resistant to plague infection, but not sufficiently so as to allow the development of permanent pockets of the disease, and plague in India appears to be epidemiologically unstable and will presumably die out unless infection continues to be reintroduced.^{4, 106} Introduction of infection into a healthy area can occur only where *R. rattus* is present, the epizootic is brief unless the more resistant *R. novegicus* is present, and these domestic rats serve to infect the wild rodent population.

The prominent role of the human body louse in epidemic plague in man points up the significance of disinfestation as a control measure, together with chemoprophylaxis, in epidemics. In the longer view, control of the rat population will prevent introduction of new infection and reduce the probability of human infections initiating epidemic spread. Control of wild rodent plague is a difficult matter, but encouraging results have been reported from Russia.³⁹

Bacteriological diagnosis.⁷ In man the bacilli are found in material aspirated from

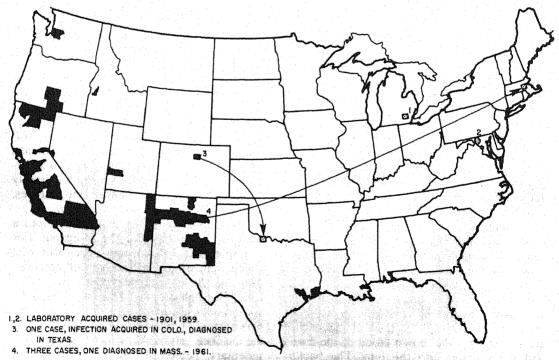

Figure 133. The occurrence of human plague in the United States as indicated by counties reporting one or more cases in the period 1900-1965. (Morbidity and Mortality Weekly Report, Annual Supplement, Vol. 14, No. 53. Communicable Disease Center, Public Health Service, U. S. Department of Health, Education, and Welfare.)

buboes, in cultures or smears of internal organs, especially the spleen, and, in pneumonic plague, in the sputum. The presence of gram-negative, bipolar-staining, ovoid bacilli is highly suggestive. Blood cultures, taken late in the disease, should be cultured first in broth. Other material may be inoculated directly on blood agar and glycerol agar. An enriched azide-antibiotic-dye selective medium has been developed for isolation of the bacilli from highly contaminated material such as soil.72 Cultures may be identified by cultural and biochemical characteristics and by agglutination in plague antiserum. The bacilli show some tendency to spontaneous agglutination, and the slide agglutination test is unsatisfactory. Postmortem diagnosis may be made by tapping the liver, lungs, and buboes, if present, with a syringe. The serous fluid is used for preparing smears and, after dilution in saline, for the inoculation of guinea pigs. Microscopic examination of smears often gives almost unequivocal diagnosis, and fluorescent antibody staining may be useful when specimens are too grossly contaminated for culture or animal inoculation. 56 Animal inoculation should always be carried out when possible.

Guinea pigs may be inoculated subcutaneously or, with specimens that have undergone gross contamination and decomposition. by rubbing the material on the freshly shaved abdomen; the plague bacilli penetrate the minute abrasions whereas the contaminants do not. The animals die in two to five days; postmortem findings are characteristic and include subcutaneous and general congestion, congested spleen, granular liver, and pleural effusion. The bacilli may be found in spleen smears and elsewhere and cultured. It is important that the animal be freed of ectoparasites before inoculation. Plague in rodents may be diagnosed by postmortem findings, which are similar to those in the guinea pig, by microscopic and cultural demonstration of the bacilli and by guinea pig inoculation. Of the serological reactions, passive hemagglutination appears to be the most sensitive. 74, 90

Chemotherapy. 83, 86 Streptomycin and sulfadiazine appear to be the most effective chemotherapeutic agents in plague. Prophylactic inoculation with sulfadiazine or

sulfamerazine is reasonably effective for the protection of contacts. For therapeutic purposes, streptomycin is given for the first four to five days and then replaced by sulfonamide. In severe septicemic and/or pneumonic plague, the streptomycin may be supplemented with oral chloramphenicol or tetracyclines and antiserum prepared in the rabbit.

Immunity. 87, 88 Recovery from plague confers a solid immunity to subsequent infection. In this immunity phagocytosis appears to be of primary importance, functioning through opsonization to counteract the antiphagocytic properties of the envelope or capsule of the bacillus. It is probable that antibody to the envelope antigen, Fraction 1, plays a significant part in an effective immunity, and that to the VW antigen complex may be significant also. Antitoxic immunity does not contribute materially to effective immunity, and antitoxic serums are not protective.

While virulent strains are considered to be preferable for the preparation of killed vaccines, vaccines prepared with avirulent strains may also give an immunity as do certain living vaccines of avirulent strains. Various kinds of soluble preparations^{26, 66, 117} produce an immunity under experimental conditions, as indicated by protection tests in monkeys,³³ mice,¹⁴ or guinea pigs, but the immunity may not be of a high order. Differences in the response of animal species make for some difficulty in assaying immunogenic potency, *e.g.*, a preparation producing an immunity in mice may not immunize guinea pigs.

Immunization of man has been carried out with vaccines made up of suspensions of killed or attenuated bacilli or with whole culture antigen. The vaccine used by the United States Army during World War II consisted of a suspension of 2000 million formalin-killed virulent plague bacilli per milliliter, and was given in two doses, 0.5 ml. and 1.0 ml., seven to 10 days apart. The Haffkine Institute vaccine is a whole culture antigen. The plague bacilli are grown in nonantigenic casein hydrolysate medium decolorized with charcoal and containing Tween 80 to facilitate diffuse growth. It is standardized by immunogenic potency rather than by the number of bacilli con-

Inoculation with living attenuated bacilli

produces a solid immunity in experimental animals. The use of such vaccines in man has been investigated in South Africa with encouraging results, and a similar vaccine has been used in Indonesia in more than 10 million inoculations without untoward results. These vaccines have been of particular interest in Russia also.⁷³

PASTEURELLA PSEUDOTUBERCULOSIS⁷⁰

Past. pseudotuberculosis (B. pseudotuberculosis rodentium) resembles the plague bacillus closely, 121 but causes a disease of rodents, particularly guinea pigs. It is differentiated from the plague bacillus by its motility at 18°-22° C. (by stab culture in soft agar), its production of urease, and its fermentation of rhamnose and glycerol. 32, 43 It has been reported to grow abundantly as large opaque colonies on desoxycholatecitrate agar, while *Past. pestis* grows only scantily as reddish pinpoint colonies. 122 It is less virulent for the guinea pig than the plague bacillus, and produces a toxin, which differs from that of *Past*, pestis antigenically and in that rabbits and guinea pigs as well as rats and mice are susceptible to it.115 Past. pseudotuberculosis is separable into five serotypes and six subtypes. Certain of the somatic antigens are related to Salmonella antigens, and types II and IV are agglutinated by serum from persons infected with Salmonella. Diagnostic agglutination reactions must, therefore, be interpreted with caution, and serums should be absorbed with Salmonella antigen. Many of the antigenic components are shared with Past. pestis, including the VW complex.19

The natural mode of infection is probably by way of the alimentary tract. Subcutaneous inoculation of guinea pigs proves fatal in two to three weeks, with caseous swellings and nodules ("pseudotubercles," which have unfortunately given this bacterium its name) in various organs. Past. pseudotuberculosis has been found, though rarely, in animals other than the guinea pig. Human infection is rare and has been considered to be almost uniformly fatal; but less serious disease, commonly of lymphoid tissue and sometimes simulating acute appendicitis when the adenitis is mesenteric, is observed from time to time. 30, 52, 69, 116

PASTEURELLA TULARENSIS⁴¹

Tularemia is a disease of rodents, rabbits in particular, that is transmitted to man either directly through the handling of the flesh of infected animals or indirectly through an insect vector. Past. tularensis (Bacterium tularense) was discovered by McCov and Chapin in 1912 in a plague-like disease of the California ground squirrel. Tularemia in man, however, is contracted largely from the rabbit, and it was shown by Francis in 1919 that the disease known in Utah as deer fly fever is, in fact, tularemia transmitted from infected rabbits to man by the bite of the fly Chrysops discalis. Francis also found that Past. tularensis was present in rabbits sold in the markets of Washington. D.C., and that a disease known as rabbit fever was not infrequent among those in contact with the rabbits. Human cases have been observed throughout the continental United States.

Morphology and staining.48 In culture Past. tularensis is a minute, gram-negative pleomorphic rod 0.2 μ in breadth and 0.3 to 0.7 μ in length; the coccoid form predominates in young cultures and the bacillary form in older cultures. In smears from the spleens of infected mice or guinea pigs, the bacteria appear as coccoid forms in well-defined clusters. Capsules are present in the body: spores are not formed, and the microorganisms are nonmotile. The organism reproduces by a number of methods, including binary fission, budding, filament formation, and the like, and is regarded as closely related to the microorganisms of the pleuropneumonia group (Chap. Twentyseven). It is thought by some to be more closely related to Brucella than to Pasteurella and is, in fact, named Brucella tularensis by British workers; it has also been suggested that it be set apart and a new genus, Francisella, created for it.101

On solid mediums *Past. tularensis* forms minute, transparent, drop-like colonies that are mucoid in consistency and readily emulsifiable. Colonial variants, including those associated with virulence, are more sharply characterized when observed by oblique transmitted light.^{34, 35}

This bacterium is somewhat difficult to stain; methylene blue is not satisfactory, but either carbol-fuchsin or aniline gentian violet may be used. Bipolar staining may be observed.

Physiology. Past. tularensis differs sharply from the other members of this genus in that it will not grow on the ordinary mediums. It may be cultured on a coagulated egg-yolk medium or on blood dextrose cystine agar. Growth occurs in casein or gelatin hydrolysate liquid medium supplemented with biotin, blood cell extract, and liver extract, and a medium of heart infusion, dextrose, cystine, and hemoglobin will support good growth. Peptic digest of hemoglobin has been used to give a medium that is transparent rather than opaque. 42 It has also been cultivated in chemically defined mediums,81,125 spermine is required, and the pH is critical and should not be higher than 7.5. It is aerobic and facultatively anaerobic, and its optimum temperature is 37° C. Glucose, maltose, and mannose are fermented, the fermentation of glycerol, levulose, and dextrin is irregular, and mannitol, galactose, xylose, trehalose, salicin, arabinose, adonite, sucrose, lactose, amygdalin, dulcitol, erythritol, inositol, inulin, raffinose, sorbitol, and rhamnose are not fermented. Differential fermentations are of no value. It is killed by exposure to 56° C. for 10 minutes. It has been reported that this bacillus contains an endotoxin.

Pathogenicity. Two clinical types of tularemia are recognized, one the glandular or ulceroglandular type, which is the more common, the other the so-called typhoidal type. In the first instance the acute stage of the disease is characterized by headache, pains, and fever, and a papule appears,

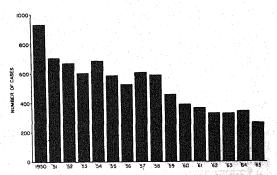

Figure 135. Cases of tularemia reported in the United States, 1950-1965. (Morbidity and Mortality Weekly Report, Annual Supplement, Vol. 14, No. 53. Communicable Disease Center, Public Health Service, U. S. Department of Health, Education, and Welfare.)

TO SEE THE COMMENT OF THE

frequently on a finger where presumably the bacilli enter the body, which later breaks down and forms an ulcer. The axillary and epitrochlear glands become painful and swollen and may break down with the discharge of purulent material. In persons infected via the conjuctiva, ulcers form on the inner surfaces of the evelids, and the cervical and preauricular glands may become tender and somewhat swollen. In the typhoidal type of the disease there are no local symptoms.

During the first week of illness the bacilli may be present in the blood and have been cultured, although, in general, cultures made directly from man are not successful, and the bacillus is best isolated by guinea pig inoculation and culture from necrotic foci found in liver, spleen, and lungs of the pig on autopsy. Direct cultivation from the blood is rarely possible but has been accomplished, and it has been suggested that during the first week of the disease initial bacteremia may occur which, in fulminating cases, develops into septicemia. The bacilli can only rarely be found in smear preparations from human cases. In the experimental disease the bacilli are present in the lymph spaces and phagocytic cells of infected tissues, and their presence within the cells in enormous numbers has caused some workers to suggest an intracellular proliferation of the microorganisms similar to that of the rickettsiae. Agglutinins are present in the blood in the second week of the disease and may persist in diminishing amounts for at least as long as 18 years after recovery. The average duration of the disease is two

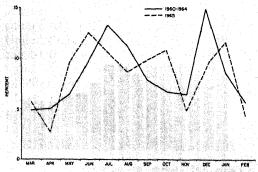

Figure 136. The seasonal incidence of tularemia as per cent of cases by the month in the United States. (Morbidity and Mortality Weekly Report, Annual Supplement, Vol. 14, No. 53. Communicable Disease Center, Public Health Service, U. S. Department of Health, Education, and Welfare.)

to four weeks. The case fatality is low, 4.8 per cent, and the pathology of the disease in man is not well known.82

A variety of lower animals have been found to be naturally infected—in addition to the ground squirrels and rabbits noted above, wild rats and mice, woodchucks, opossums, beavers, coyotes, deer, red foxes, ground hogs, muskrats, hogs, skunks, dogs, cats, and lambs. In the western United States sheep infection, with a mortality as high as 10 per cent, serves as a source of human infection. 60 The infection also occurs naturally in some birds such as sage hens. grouse, and quail.

Of experimental animals, the mouse, guinea pig, and rabbit are susceptible in that order. There appear to be two geographical varieties of *Past*, tularensis with respect to rabbit virulence, the American variety, which is the more virulent, and a European-Asiatic variety, which is less virulent; the former ferments glycerol and the latter does not.98 The LD50 of a highly virulent strain is 10 or less for any of these animals. but as virulence declines it is evident first in the rabbit, then the guinea pig, and finally the mouse.10

Epidemiology. As indicated above. tularemia is acquired by man from lower animals either directly or indirectly. The bacilli may enter the unbroken skin of the guinea pig, and possibly this may occur in man through the dressing of infected rabbits and other animals, or the microorganisms may enter by means of minute abrasions on the skin of the hand. The bacteria may penetrate the intact skin; in the mouse the LD₅₀ through the skin is two to five times that by mouth, and about 10⁷ times the parenteral dose.105 Eve infection occurs, and in fact, such infections were the first human infections with the bacillus observed. Over 90 per cent of the human cases in this country are contracted from rabbits, and it is estimated that about 1 per cent of wild rabbits are infected. Jellison and Parker⁶¹ have reported that the cottontail rabbit, species of Sylvilagus and S. floridanus in particular, is by far the most important source of infection in this country, accounting for more than 70 per cent of all human cases in North America. Many wild animals are naturally infected, and Burroughs et al. 15 have compiled a list of 48 naturally infected vertebrates. Laboratory infection is not uncommon; 56 cases acquired from dissecTULAREMIA 569

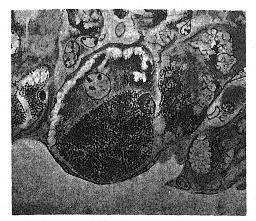

Figure 137. Pasteurella tularensis in hepatic cells of mouse. (Francis.)

tion were reported to 1940. Past. tularensis has also been found in streams and is perhaps associated with the epizootics occasionally observed in beavers. Present evidence indicates that fish cannot be infected with Past. tularensis and they probably play no part in the infection of water. Waterborne epidemics have occurred in Russia and Turkey. In this country infection of natural waters is relatively common in the northwestern states, and naturally occurring infections in beavers and muskrats are well known. In water and mud, infection may persist for many months, and available evidence suggests that the microorganisms may multiply there. 100 The infection is also transmitted by the ingestion of infected tissue¹²³ and this may be a factor too in the maintenance of the reservoir of infection in carnivorous animals.

The transmission of tularemia by an insect vector is common. In addition to the deer fly, C. discalis, Dermacentor andersoni, D. variabilis, D. occidentalis, Haemaphysalis leporis palustris, H. cinnabarina, and Ixodes ricinus californicus may carry it. In all probability the wood ticks serve to disseminate the infection in the animal population, and it is of particular interest that the infection is transmitted from the adult tick to the egg, and both the larvae and the nymphs are infectious. Tularemia may, then, be in part maintained in the insect population. In Arkansas, for example, the disease is mainly tickborne and is an occupational hazard among farm workers.

Tularemia has been found in all parts of the United States, in Japan, where it is also known as yato-byo or O'Hara's disease and in Central Europe, and extensive epidemics have occurred in Russia. Since World War II the infection has spread from southeastern Russia and Scandinavia west to the Atlantic and south to Asia Minor, and is now found in most of Europe.⁷¹

Bacteriological diagnosis. As indicated above, Past. tularensis is difficult to cultivate from infected material. Specimens should be streaked on blood-dextrosecystine agar. Characteristic minute, droplike colonies may appear in three to five days, but a culture should not be recorded as negative in less than three weeks. The procedure of choice is the intraperitoneal inoculation of a guinea pig with a saline emulsion of the specimen; relatively large amounts are required, usually 4 to 8 ml., of a fairly heavy emulsion. The animal should die in five to 10 days. The pathology is characteristic and includes hemorrhagic edema without pus at the site of inoculation, enlargement of the cervical, axillary, and inguinal lymphatics which contain dry caseous material, and small white necrotic areas in the liver and spleen. Smears and cultures may be made, but not infrequently the bacilli cannot be found or cultivated. In such instances the diagnosis depends on the guinea pig pathology.

Isolated cultures may be identified by specific agglutination. Conversely, patient's serum may be tested for agglutinins; a titer of 1:80 or higher is usually regarded as diagnostic if there are no Brucella agglutinins. In the event that Brucella is also agglutinated, the agglutination of *Past. tularensis* occurs more rapidly and to higher titer in tularemia.

Chemotherapy. The sulfonamides are almost completely ineffective chemotherapeutic agents in tularemia. Of the antibiotics, streptomycin has been found highly effective, subject to the rapid acquiring of drug resistance by the microorganisms; the tetracyclines are effective, but chloramphenicol has only slight activity.

Immunity. An attack of tularemia confers an effective immunity, but it is not as solid as once thought. Two extremely well documented cases of reinfection among laboratory workers have been reported by Green and Eigelsbach. Both had been immunized with vaccine; one subsequently acquired two clinical infections within three years, and the other, two infections within six years. Similar experiences have been

reported by others. 85 The relation of antibody response to effective immunity is not clear; in any case agglutinin appears not to be closely related to protective antibody. Antibodies (agglutinins) to *Past. tularensis* show some cross-reaction with *Br. meliten*sis and *Br. abortus*. Prophylactic inoculation with vaccines is not successful in experimental animals in that it does not protect against the injection of virulent strains. There is some evidence, however, that vaccine prophylaxis in man confers a useful degree of protection. 63, 113

Actinobacillus

The microorganisms grouped within the genus Actinobacillus are, like Mycobacterium (tubercle and related bacilli) and Corynebacterium (diphtheria and diphtheroid bacilli), more closely related to the fungi than many other bacteria. Nevertheless, they are classified with the Eubacteriales under the tribe Brucelleae, together with Brucella, Pasteurella, and Hemophilus, The distinctions between these last three are not sharp, and some of these bacteria are put in one genus by some workers, and in another by other workers. The microorganisms of the genus Actinobacillus tend to be set somewhat apart and include the causative agents of glanders and melioidosis, together with forms found in association with actinomycetes in certain kinds of actinomycosis (Chap. Thirty-two), producing disease which closely resembles certain of the fungous infections, known as actinobacillosis.

THE GLANDERS BACILLUS (ACTINOBACILLUS MALLEI)

Glanders is a disease seen, as a rule, only in the solipeds (horse, mule, ass) but is occasionally transmitted to other domestic animals, to wild animals, and to man. Early regarded by many as a spontaneous, non-infectious disease, the transmissibility of glanders was demonstrated in 1837 by Rayer, who infected a horse by inoculating it with material from a case of glanders in a human subject. The causative bacillus was discovered in 1882 by Löffler and Schütz, whose work was confirmed and extended by Kitt, Weichselbaum, and others.

Morphology and staining. The glanders bacillus is a small rod, straight or slightly curved, usually with rounded ends, and often of irregular contour. Rather wide variations

in size are observed; the average length may be taken as 2 to 5 μ and the average breadth 0.5 to 1 μ . In culture the bacillitend to be shorter and more uniform in size than those observed in pus smears. In pus they are sometimes found within the leucocytes but more often occur free. There is no special arrangement in such smears, but in culture the bacilli may occur in pairs and, in older cultures, produce filaments with swollen ends in which true branching may be observed. The bacilli are nonmotile and nonencapsulated, and do not form spores.

Colonies on agar are small, round, convex and amorphous in consistency. They are translucent and yellowish in color and upon aging (eight to 10 days) become more opaque, and the center may become light brown. The growth on potato usually exhibits a characteristic appearance; clear, amber,

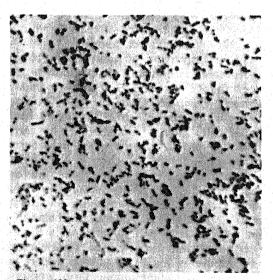

Figure 138. Actinobacillus mallei in pure culture. The generally poor staining is apparent, and bipolar staining may be observed in some of the cells. Methylene blue; × 1250.

honey-like colonies appear and may coalesce, and frequently the potato around the growth becomes tinged a greenish yellow, not unlike the discoloration produced by *Pseudomonas pyocyanea*. On horse blood agar the colonies are grayish green with browning of the medium but no hemolysis.

The glanders bacillus stains with the ordinary aqueous aniline dyes, though not readily. Best results are obtained with stains containing alkali, or a mordant such as phenol (Löffler's alkaline methylene blue. Ziehl's carbol-fuchsin). The bacilli are not acid-fast and are gram-negative. Cells from young cultures take the stain fairly uniformly, but those in older cultures stain irregularly, with a tendency to bipolar staining. Granules and coccus-like bodies within the cell take the stain somewhat more readily, and the bacilli have a beaded appearance in stained preparations. This irregular staining is due to the presence of lipid granules which do not stain with the usual dyes but may be demonstrated with Sudan black B or iodine-fuchsin.

Physiology. Growth occurs on ordinary nutrient mediums but is poor and slow on primary isolation. Forty-eight hours' incubation is generally necessary for the appearance on solid mediums of colonies 0.5 to 1 mm. in diameter. Growth is materially enhanced by the presence of glycerol, but glucose is without effect. A slightly acid reaction is favorable, and the optimum temperature is 37° C., though growth may occur over the range of 22° to 44° C. Growth on enriched mediums such as Löffler's serum medium or horse-blood agar is not markedly better than on glycerol agar. 91

The glanders bacillus is quite inactive biochemically. With the exception of glucose there is no action on the usual carbohydrates, and even the glucose fermentation is irregular and variable from strain to strain. Coagulated serum is not digested, but gelatin may be liquefied under appropriate circumstances by some strains at least. At temperatures at which gelatin remains solid, growth is sparse and no liquefaction is observed, but if cultures are incubated at 37° C. for 26 to 40 days, the gelatin does not solidify on cooling. Indol is not produced, and nitrates are not reduced to nitrites; small amounts of hydrogen sulfide may be formed. Slight acid production sometimes occurs in milk, with coagulation by the tenth day of incubation and decolorization of the indicator in the lower part of the tube.

The bacillus is but slightly resistant to adverse physical and chemical agents, being readily killed by heat (55° C. for 10 minutes) and bactericidal chemicals. The most effective disinfectants are hypochlorites, iodine, and mercuric chloride. Desiccation experiments have not given uniform results; it is said that cultures dried on threads remain viable for three or four weeks. Pure cultures appear to be more resistant to desiccation than the bacilli in the nasal secretions from diseased animals, for infected discharges are usually sterile within a few days. Cultures die out in four to six weeks but may be maintained by transfer on glycerol agar.

Classification. The relation of the glanders bacillus to other bacteria is by no means clear. In certain respects, such as the occurrence of branching and the favorable effect of glycerol on growth, it resembles the Mycobacteria though it is not acid-fast. In other respects it is related to the Pasteurella species with which it is grouped as Actinobacillus.

Pathogenicity for lower animals. Under natural conditions the horse is chiefly affected, but cases are occasionally observed in the carnivora (cats, dogs, menagerie animals) and in goats and sheep. Swine and pigeons are slightly susceptible. Cattle and house rats are immune. Rabbits and guinea pigs are somewhat susceptible to experimental inoculation, and the hamster and ferret are the most susceptible of the usual experimental animals.⁹²

The route by which the glanders bacillus usually enters the body of the horse has not been clearly determined. The mucous membrane of the nose, especially if slightly abraded, may become the portal of entry, as may the intact conjuctiva, which can be infected by contact with infectious material in two to four hours, sometimes in 30 minutes. Infection by inhalation must be rare, to judge from animal experiments. According to Nocard, infection occurs by way of the alimentary tract in the great majority of cases

Glanders manifests itself in an acute and a chronic form, which run into one another, the latter frequently terminating in an acute attack. The acute form is ushered in usually by a chill and the appearance of a high temperature in advance of any local manifestation. In a few days the mucous membrane of the nose is inflamed and becomes studded with nodules, the lymphatic system becomes largely involved, and edematous swellings appear in various parts of the body. General symptoms become more grave, and death follows in from eight to 30 days. The mule, and especially the ass, suffer commonly from the acute disease. The chronic form is the more usual type in the horse (90 per cent of cases). A great variety of symptoms and lesions have been noted in the latter animal, and the disease pursues most diverse courses in different individuals. The nasal membrane is often affected, and there is a profuse and infectious catarrhal discharge. Cutaneous glanders is known by veterinarians as farcy, the thickenings of the superficial lymphatics being termed "farcy buds" or "farcy pipes." In all forms of glanders there is a tendency to the production of nodules, which soften and pass over into ulcers. The glanders nodule has been considered by some writers to be structurally similar to the nodule formed by the tubercle bacillus (Chap. Thirty), but most observers agree that the former is a degenerative rather than a proliferative formation and that it is radically different from the tubercle.

Experimental inoculation with pure cultures has given positive results not only in the horse, in which the characteristic features of the disease are reproduced, but in guinea pigs, field mice, and other small rodents. The guinea pig is the animal commonly used for diagnostic purposes. Both in the natural and in the experimental infection the bacteria are found chiefly in the nasal secretions and in the contents of the young nodules; in the older ulcers they are relatively few in number. The blood, as a rule, contains glanders bacilli only in acute general infection.

Pathogenicity for man. Veterinarians and others having to do with the care of horses are the most liable to contract glanders. Freshly isolated cultures are highly virulent, and a number of fatal infections have occurred among laboratory workers. The acute form of the disease is the more common in man, most cases terminating fatally within two or three weeks, sometimes within a few days of their inception. As in the horse, the mucous membrane of the nostrils is often, although not invariably, affected. Occasionally the chronic form may

appear and linger for months or even years, with spreading ulceration and other features closely resembling those observed in the horse. Recovery from chronic glanders may take place, or the disease may pass into the acute stage. 55, 84, 99

In man the alimentary tract is certainly not the ordinary channel of entrance; meat from glandered animals has been ingested without resulting infection. Infection probably occurs through abraded skin.

Bacteriological diagnosis. In prebacteriological days chronic glanders in the horse was frequently separated from other diseases only with difficulty and a considerable measure of uncertainty. At present the diagnosis of glanders is greatly facilitated by (1) guinea pig inoculation; (2) the mallein test—(a) subcutaneous, (b) ophthalmic; (3) the agglutination method; (4) the complement-fixation test.

(1) Guinea pig inoculation. A male guinea pig is injected intraperitoneally with fragments of diseased tissue, scrapings from ulcers, or some of the nasal discharge from a suspected animal. A positive reaction is shown by the testicles becoming red and swollen, usually on the second or third day-the Straus reaction. Together with the orchitis (inflammation of the parenchyma of the testicle) there are severe general symptoms which usually culminate in 12 to 15 days. Gravish nodules are often found in the spleen and other internal organs. The test is not absolutely specific, for Kutscher and Nocard have shown that an analogous orchitis may be produced by other organisms besides the glanders bacillus.

(2) The mallein test. Mallein is the concentrated glycerol broth in which the glanders bacillus has grown; it is prepared in the same manner as tuberculin. The mallein reaction consists in a rise of temperature, accompanied by a pronounced local reaction, and in many cases, though not invariably, by more or less profound constitutional disturbances.

(a) Subcutaneous injection of mallein (the size of the dose varying according to the concentration) into a glandered horse is followed by the signs noted above, while in an animal not infected with glanders the temperature is slightly or not at all affected and the general symptoms are absent.

(b) The ophthalmic test consists in the introduction of the mallein, preferably in tablet form, into the conjunctival sac.

The conventional serological reactions. agglutination and complement-fixation.29 tend to give erratic results in that infected animals may show no evidence of antibody formation, and normal serum titers may be relatively high; normal horses, for example, may have agglutinin titers as high as 1:500. Serology is complicated by the fact that the antigenic structure of the bacteria is not established beyond early reports that there is some antigenic heterogeneity.

Chemotherapy. Glanders occurs rarely that little is known concerning its chemotherapy. It has been reported that two chronic cases and six laboratory infections were successfully treated with sulfadiazine.

Immunity and prophylaxis. Permanent immunity to glanders can neither be conferred by an attack of the disease nor produced by artificial means. Nocard fed infectious matter to three horses which had previously recovered from the disease and found that these animals showed no resistance superior to that of a healthy control animal. Similarly, Lobel, Schaar, and Roza⁷⁹ were unable to produce an immunity in guinea pigs or horses by the inoculation of bile-attenuated avirulent bacilli. Chronic glanders may exist for years and is in no wise a warranty against the sudden development of an acute attack.

No very potent or characteristic toxic substance has been obtained from cultures of the glanders bacillus, and attempts at immunization with the products of this organism have been eminently unsuccessful. It is stated by a number of observers that repeated injections of mallein will exercise a curative action upon certain forms of recent infection, but experimentally mallein is without immunizing power. The serums of animals treated with mallein injections and the serums of naturally immune animals such as cattle are, according to most observers, totally devoid of any preventive or curative value. The most that has been accomplished in the way of immunization is a very moderate augmentation of resistance in dogs injected with small nonfatal doses of living cultures.

The experience of Great Britain shows that the disease may be practically eradicated by slaughtering every animal showing clinical signs of glanders, or a positive mallein test, and properly disposing of the carcass.

WHITMORE'S BACILLUS

Melioidosis, a disease of rodents somewhat similar to glanders, is caused by a microorganism variously known as Actinobacillus whitmori, A. pseudomallei, and, more recently, Pseudomonas pseudomallei. The disease occurs in the southwest Pacific area, e.g., in Burma, Thailand, Vietnam, and Indonesia, and in Australia as a disease of sheep, cattle, swine, and horses. It occurs in man in these areas,12,67,111 and has apparently been locally acquired in the

Western Hemisphere.9

Whitmore's bacillus differs from A. mallei in that it is motile, liquefies gelatin, and actively ferments carbohydrates. It grows considerably more rapidly, and its colonies on glycerol agar develop a wrinkled, corrugated surface and are quite different in appearance from those of A. mallei. A second colonial type may be produced, however, which is very similar to the colonies of the glanders bacillus. It is thought by some to be closely related to Ps. aeruginosa in many respects, and strains have been reported which produce pyocyanin. It has been reported that two thermolabile exotoxins are produced, one lethal and necrotizing, and the other lethal only.28,46 A heat-stable endotoxin, closely resembling those of the enteric bacilli and eliciting the Schwartzman reaction, has been described also. 108 An aggressin activity, apparently polypeptide in nature, has been found in sonic lysates of the bacilli; although not toxic itself, when given concurrently with the challenge inoculum it markedly increases mortality.76,80

Melioidosis in man may assume three general forms: an acute septicemic condition with diarrhea, a subacute typhoidal form with pulmonary symptoms and local abscess formation, and a chronic form which may localize in any tissue, including bone, to produce osteomyelitis, as small caseous nodules which may coalesce. It was formerly believed that the case fatality rate in man was very high, 95 per cent or more, but this is presumably applicable only to the untreated, acute form. More recent serological evidence⁹⁶ indicates that the infection may be much more common, and milder, than had been supposed. CONTRACT TO A SCHOOL OF

The tetracyclines appear to be the most active of the chemotherapeutic agents when tested in vitro, 95 but the experimental disease in mice is most effectively treated with chloramphenical or sulfonamides, the tetracyclines requiring extended periods of treatment to give 70 per cent or better cures. 49

Transmission of the infection among guinea pigs by biting insects, mosquitoes, and fleas, has been reported. Rodents usually die within a short time from septicemia, and the lesions appear as small nodules superficially resembling tubercles. Guinea pigs and rabbits are highly susceptible to inoculation, and the Straus reaction is produced.

ACTINOBACILLOSIS

Actinobacillus lignieresi. In 1902 Ligniers and Spitz isolated a nonmotile, nonbranching, nonacid-fast, gram-negative bacillus from the lesions of a disease of cattle which closely resembles actinomycosis and with which it is frequently confused. The microorganism is known as A. lignieresi and the disease as actinobacillosis. Originally found in Argentina, it appears to be relatively common and has been recognized in Europe and in this country.

Granules, very similar to but smaller and more numerous than the "sulfur granules" of actinomycosis, are found in the thick pus from the lesions. These granules or colonies contain clubs radially arranged about a center which is composed of detritus and gram-negative bacilli. The microorganism is pleomorphic in cultures; diplococci and slender rods are found in smears from cultures in liquid mediums, while long curved forms are present in deep colonies in agar mediums. The bacilli are $0.4~\mu$ in diameter and 1 to 15 μ in length.

Surface colonies on laboratory mediums are small, 0.5 to 1 mm. in diameter, smooth, glistening, convex, bluish white, and delicate in appearance. In liquid mediums, such as serum-glucose-broth, the growth consists of small grayish granules adhering to the sides of the tube and readily broken loose by shaking; the broth does not become turbid. The microorganism appears to be a strict parasite and grows very poorly or not at all except in mediums containing serum or whole blood. It is an obligate aerobe though primary cultures are often more successful in fluid mediums or serum-glu-

cose-agar stab cultures, especially when incubated in an atmosphere containing 10 per cent carbon dioxide. Cultures grow up in 24 hours at 37° C.; growth is very slight at 20° C. Dextrose, lactose, sucrose, maltose, raffinose, and mannitol are fermented; the fermentation of xylose is irregular. Arabinose, dulcitol, salicin, and inulin are not fermented. Very small amounts of indol are produced, coagulated serum is not liquefied, and litmus milk is usually unchanged but is sometimes slightly acid.*

As indicated above, the disease in cattle closely resembles actinomycosis, differing in that the bones are seldom affected and the lesions are found in the soft tissues, the regional lymphatics being commonly involved; the subcutaneous tumors break down in time to form abscesses. The subcutaneous lesions respond to surgery, but infection of the tongue, "wooden tongue," is often fatal. The disease has been observed to occur in both epizootic and sporadic form. It is readily reproduced by inoculation of cattle, but the microorganism is only feebly pathogenic for the usual experimental animals; massive intraperitoneal inoculation of the guinea pig produces a scrotal reaction similar to the Straus reaction. A very few probable cases of human infection have been reported.40

Actinobacillus actinoides. 68 This microorganism was originally isolated from the lungs of calves suffering from chronic pneumonia and later from a similar affection in white rats. It is not pathogenic for other experimental animals, and, in fact, its etiological relationship to the observed disease is questionable.

Actinobacillus actinomycetem - comitans. This bacillus has been observed and isolated from human cases of infection with Actinomyces bovis, first by Kligler in Germany in 1912, and by Comstock in England in 1920, and Bayne-Jones in 1925 in this country. It occurs as densely packed, gram-negative coccobacilli in contrast to the gram-positive actinomycete mycelium in the interior of the sulfur granules. It has never been reported in bovine actinomycosis, and the significance of its presence is open to question.

Challenger in

^{*}There is some discrepancy in the literature on these points.

Chapter Twenty-six

THE HEMOPHILIC AND RELATED BACTERIA

The hemophilic bacteria are characterized by a nutritional requirement for constituents of fresh blood, especially hemoglobin and certain related compounds, or the X factor, and/or a requirement for the heat-labile V factor which may be replaced by NAD or NADP. Not all bacteria grouped under the genus Hemophilus have these nutritive requirements, notably the pertussis bacillus, the Morax-Axenfeld bacillus and Ducrey's bacillus, but they are otherwise similar. They are related antigenically to certain of the Brucella species, such as Br. bronchiseptica as noted elsewhere and lines of distinction may be difficult to draw. The pertussis bacillus has, in fact, been placed in a separate genus, Bordetella, by some.

The Hemophilic Group

SPECIES	GRO' REQUIR	HEMOL-

H. duplex (Morax-Axenfeld)	÷.		.
H. ducreyi			• • •

HEMOPHILUS INFLUENZAE (PFEIFFER'S BACILLUS)

Hemophilus influenzae was isolated by Pfeiffer in 1892, and until the early 1930's was regarded by many as the etiological agent of epidemic influenza. Influenza has, however, been shown to be caused by a virus, and the name influenzae has no etiological significance.

Morphology and staining. Pfeiffer's bacillus is one of the smallest pathogenic bacteria, rarely exceeding 1.5 μ in length and 0.3 μ in thickness. The ends of the cell are rounded, capsules are not generally observed but are present in smooth cultures, spores are not formed, and the bacillus is nonmotile. There is a marked tendency to produce threads and other anomalous forms in culture which is, to some degree, a characteristic of strains. Some workers have attempted to differentiate varieties on the basis of morphology, but there is a continuous series of types, ranging from precoccobacillary dominantly forms predominantly longer bacilli and threads, and no sharp distinction can be made. There is a tendency, however, to regard the coccobacillary forms as "typical" and the longer forms as "atypical"; the typical form appears to predominate in strains isolated from pathological processes.

On blood agar the colonies of Pfeiffer's bacillus are very small, rounded, discrete, and transparent and may reach the size of a small pinhead. If the culture is contam-

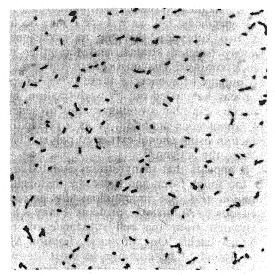

Figure 139. Hemophilus influenzae, pure culture. Note the variability from coccoid to bacillary form and the presence of longer filaments. Fuchsin; × 1050.

inated with other microorganisms, especially Staphylococcus aureus, the colonies are considerably larger, more opaque, and of a grayish white color, and develop most luxuriantly in the neighborhood of the foreign colony, a phenomenon termed the satellite phenomenon.

These bacilli are somewhat more difficult to stain than most bacteria: Löffler's methylene blue for five minutes or dilute (1:10) carbol-fuchsin for 10 minutes is satisfactory. They are gram-negative.

Physiology. One of the more fastidious bacteria, Pfeiffer's bacillus requires, as noted above, the presence of blood in the culture medium. It has been found that two substances present in such blood mediums are necessary to the growth of this bacterium; one, designated the "X factor," is heat-stable and associated with hemoglobin, and the other, the "V factor," is heat-labile and is found in yeast and various vegetable extracts as well as in whole blood. The satellite phenomenon noted above is due to the formation of the V factor by other bacteria and its diffusion into the medium from the colony.

The X factor is replaceable by hemoglobin or hematin. The iron protoporphyrin can be replaced with certain other iron porphyrins, but not by porphyrins such as meso-, hemato-, deutero-, and coproporphyrins. These last suppress growth by a competitive inhibition,28 and such activity is eliminated by methylation of the propionic acid side chains.24 It seems that these or related compounds are required for respiration-some strains do not require it for anaerobic growth. It has been suggested that hematin is required for the synthesis of catalase; hematin can be replaced by cysteine which would reduce peroxide and make catalase unnecessary.20

The V factor may be replaced by coenzyme I or coenzyme II but not by nicotinic acid or its amide. Apparently the whole coenzyme molecule must be supplied, and it is assumed that the thermolabile substance is of this nature. Some strains require 1.4diaminobutane, the active residue available in putrescine, spermine, and spermidine. Other growth requirements include pantothenic acid, thiamine, and uracil, and some strains require purine also.26 Some strains of H. influenzae, and H. parainfluenzae, have been grown in defined mediums.9, 58

A number of mediums have been devised for the cultivation of the influenza bacillus. Avery's oleate hemoglobin agar, prepared by the addition of sodium oleate and a suspension of erythrocytes to an infusion agar base, is one of the best of these, for not only is the growth of H. influenzae enhanced, but the growth of streptococci and pneumococci and some other bacteria present in the sputum and nasal mucus is inhibited. The influenza bacillus grows luxuriantly chocolate agar, prepared by the addition of fresh blood to hot (90° C.) infusion agar, and heavy growths for agglutination and other purposes may be obtained, but this medium does not differentiate and hence is not especially suitable for primary isolation. Fildes' agar, an infusion agar base to which has been added a peptic digest of blood, supports good growth of the influenza bacillus and is used especially by British workers.

No growth occurs on gelatin. Milk, containing blood, is rendered slightly alkaline by some strains. Nitrate is reduced to nitrite. Some strains-about 50 per centform indol. Fermentation reactions are variable, some strains being inactive while others ferment dextrose and other carbohydrates. Some strains are hemolytic while others are not. The hemolytic strains of H. influenzae do not appear to be clearly marked from the nonhemolytic strains by any other differential characters, since indol production and carbohydrate fermentation occur in both groups.

The influenza bacillus shows little resistance toward external conditions. It is readily killed by drying, and pure culture suspended in water and then dried on silk threads dies within 24 hours but in dried sputum viability persists somewhat longer, but not, as a rule, beyond 48 hours. The bacilli are readily killed by disinfectants. Even under favorable conditions artificial cultures soon die out, and, in order to preserve vitality, subcultures must be made every four or five days; chocolate agar is suitable for maintaining stock cultures.

Varieties. Subdivisions of *H. influenzae* have been made by a number of workers, but whether such varieties deserve the dignity of species standing is open to question. The morphologically "typical" and "atypical" forms have been noted above, but these are not regarded as separate species. Other distinctions which have been made on the basis of hemolysis and nutritive requirements may be summarized briefly:

(1) The hemolytic and nonhemolytic varieties. The nonhemolytic form is designated *H. influenzae* by Bergey and the hemolytic form *H. hemolyticus*. Both require the X and V nutritive factors. These are generally regarded as a single species, *H. influenzae*.

(2) The swine influenza bacillus, *H. influenzae suis* or *H. suis*, which closely resembles Pfeiffer's bacillus except that it is relatively inert biochemically and differs immunologically. This bacterium, in association with a virus, is causally associated with swine influenza. Both X and V factors are required for growth.

(3) The para-influenza bacilli, *H. parainfluenzae*, which closely resemble *H. influenzae* except that only the V factor is required for growth and these bacteria may be cultivated on agar containing serum or ascitic fluid. Although these bacilli are defined as nonhemolytic, hemolytic strains showing the same nutritive requirements are found.

(4) H. canis (H. hemoglobinophilus, H. hemoglobinophilus canis), found in the preputial secretions of dogs. It closely resembles H. influenzae except that it requires only the X factor for growth.

Variation and antigenic structure. As tested by direct agglutination, *H. influenzae* is antigenically heterogeneous, and rough and smooth forms occur in which the smooth form is encapsulated. By means of the agglutination test the encapsulated bacilli are found to fall into six immunological types, designated a, b, c, d, e, and f, and the antigens responsible are specific polysaccharides.³⁵ One of these, the type-specific substance of type b, is a polymer of ribose phosphate with a structure analogous to that of pentose nucleic acids in which the purine and pyrimidine portions are replaced

by a second polyribose phosphate chain in 1:1' glycosidic linkage.⁵⁹ Type e may occur as two subtypes, the one as occasional freshly isolated strains, and the other in stock strains.⁵⁷ Diagnostic antiserums may be prepared for each of these types.¹ Typing may be carried out by agglutination, by specific capsular swelling in the presence of homologous antibody, or as a precipitin reaction using phenol-extracted polysaccharide as the antigen.³⁴

It appears that many strains isolated are in the rough form, and these, by the agglutination test, are immunologically heterogeneous. Antigenic proteins may be extracted from the cell substance of influenza bacilli. One of these, fraction M, was found to be common to most strains of H. influenzae, indicating an immunological homogeneity demonstrable by precipitin tests with appropriately prepared antigens. It will be clear that the antigenic structure of H. influenzae is by no means fully understood as yet.

The influenza bacilli appear to be immunologically related to certain of the pneumococcus types; type a shows cross-reactions with pneumococcus type 6b and type b cross-reacts with pneumococcus type 6 and type 29.

The S-R dissociation is to some degree reversible by growth in the presence of anti-R immune serum. The relation of virulence to this dissociative change is not known.

Toxins. As in the case of many other bacteria, the cell substance of the influenza bacillus is toxic to experimental animals, mice in particular, upon parenteral inoculation. Toxic substances are produced in fluid cultures, are filterable, and may appear in appreciable quantities after six to eight hours' incubation. Relatively large quantities of the filtrate (2 to 4 ml.) are necessary to produce death in rabbits, and it is probable that a true exotoxin is not formed.

Pathogenicity for man. The pathogenicity of Pfeiffer's bacillus for man is shown by the occurrence of cases of meningitis, mostly in infants and of a high fatality, in which H. influenzae is found in pure culture in the cerebrospinal fluid. The organisms persist in nasopharyngeal carriers, with a frequency of perhaps 2 to 3 per cent. As in meningococcal infections, the carrier rate is higher when disease occurs, as in an infected household. H. influenzae meningitis is the fourth

commonest form of purulent meningitis; it occurs most often the second six months of life, and the case fatality rate in untreated cases is between 90 and 100 per cent. In one series of 758 cases of meningitis occurring between 1930 and 1953, *H. influenzae* type b was the causal agent in 128.³¹ Occasional cases of otitis media, appendicitis, sinusitis, and other localized infections may be caused by this bacterium.

The influenza bacilli are frequently present in infections of the respiratory tract and are found on autopsy in pneumonic lesions under conditions where its pathogenicity is clearly indicated. They have also been associated with respiratory disease in premature infants,14 and serological studies suggest that they may be a factor in chronic bronchitis. 21 Whether they are present as a primary or secondary invader in these cases is more uncertain. Their common occurrence in diseases such as measles, whooping cough, and tuberculosis has been taken to suggest that their growth on human tissue is favored by the presence of other infecting agents. It seems probable that in respiratory infections H. influenzae is not the primary agent.

The relation of this bacillus to influenza is very likely that of a secondary invader to the initial virus infection. It has been found that in double infections of the chick embryo with influenza virus, the pathogenicity of *H. influenzae* is enhanced though that of the virus is not affected.⁸ It is frequently but not invariably present in cases of influenza and, of course, occurs in the absence of this disease. In the case of swine influenza, the influenza bacillus is, in association with a filterable virus, causally related to the disease.

Chemotherapy. Chemotherapy has been of greatest interest in connection with H. influenzae meningitis which, in untreated cases, is almost always fatal. Penicillin is not effective, but sulfonamides, streptomycin, and chlortetracycline, sometimes in combination with antiserum, may be highly effective.7, 11, 36 In one series of cases studied,31 for example, treatment with sulfonamide alone gave 15 per cent survival and in combination with antiserum 83 per cent survival, but complications including mental retardation, blindness, hydrocephalus, and convulsions occurred in 20 per cent of survivors. The rise in recovery rate, due to more effective therapy, has resulted in an increase in such complications, i.e., in patients who would otherwise have died. A combination of sulfonamide, streptomycin, and antiserum gave a case fatality rate of 7.4 per cent, and of chlortetracycline and sulfonamide 4.3 per cent, but with the same incidence of complications. Treatment with sulfonamide, streptomycin, and chlortetracycline, occasionally reinforced with chloramphenicol, reduced the case fatality rate to 3.2 per cent and the incidence of complications in survivors to 5 per cent. H. influenzae is not sensitive to penicillin, and in fact the first use to which this antibiotic was put was that of a selective agent incorporated in isolation mediums.

Pathogenicity for lower animals. Except in swine influenza, the influenza bacillus is probably not a natural pathogen of lower animals. Upon intraperitoneal inoculation into laboratory animals-mice, guinea pigs, and rabbits-large doses of these bacteria produce death within one or two days. Whether this is an actual invasion rather than a toxemia is uncertain: the bacilli may be found in the peritoneal exudate but usually not in the heart's blood, and petechial hemorrhages may be observed scattered over the peritoneum and, sometimes, the pleura. Certain strains produce a fatal infection in mice on intracerebral inoculation. As tested by intraperitoneal inoculation, the virulence of H. influenzae varies greatly from strain to strain; the virulent strains are in a minority, and strains from influenzal meningitis are generally among the more virulent.

Other hemophilic bacteria have been described in connection with diseases of lower animals. H. canis, for example, has been found in association with inflammation of the prepuce in dogs but is apparently harmless. Other hemophilic bacilli such as H. bovis, H. gallinarium, H. muris, and H. ovis have been isolated from lower animals. Their relationship to H. influenzae and other better-known species is not clear.

THE KOCH-WEEKS BACILLUS

A small bacillus, first observed by Koch in 1883 in a series of eye inflammations in Egypt, was successfully cultivated by Weeks in New York in 1887, and is now recognized as the cause of a world-wide and highly

contagious form of conjunctivitis sometimes known as pink-eye. The disease is especially prone to occur in tropical and subtropical climates, and may assume epidemic form.⁵¹

This microorganism is a gram-negative, nonmotile, nonencapsulated facultative aerobe, and sometimes shows bipolar staining. It requires the X and V factors for growth. There is no hemolysis on blood agar, and the colonies are small and translucent with a bluish tinge in transmitted light.

This bacillus is closely related to *H. influenzae* and has been regarded by many as identical with it. Pittman and Davis⁴² have found, however, that strains of this organism make up a closely related but not homogeneous serological group, distinct from the heterogeneous nontype-specific *H. influenzae*, and differentiate it as *H. aegyptius*. Antigenic components are, however, shared with *H. influenzae*, and are demonstrable by the gel-diffusion method,⁴⁰ and a high degree of genetic homology between the two is indicated by the DNA-mediated transfer of antibiotic resistance.³³

It produces conjunctivitis in man but not in laboratory animals. It has low virulence for mice when inoculated in mucin suspension, a high virulence for the eight day chick embryo, but not for the 12-day embryo.

HEMOPHILUS PERTUSSIS (BORDETELLA PERTUSSIS)

Bacilli resembling H. influenzae were reported by early observers as occurring in a large proportion of cases of whooping cough. Although there are minor differences in the descriptions of these organisms as given by different observers, the cultural and morphological characters are essentially similar, and there seems little doubt that Spengler, Jochmann and Kraus, Wollstein. and Davis discovered the same bacillus. More definite results were obtained by Bordet and Gengou in 1908, who found in the bronchial exudate from patients with whooping cough a characteristic short oval bacillus which grew feebly on a special medium they devised. Earlier named Bacillus pertussis, this microorganism is now known either by that name or as H. pertussis or, more casually, as the Bordet-Gengou bacillus.

Morphology and staining. The Bordet-Gengou bacillus is a small ovoid rod from 1.0 to 1.5 μ in length and 0.3 to 0.5 μ in breadth. The majority of the bacteria occur singly, although they may occasionally be seen in pairs end to end; chains do not occur in smears of bronchial exudate, but short chains may be seen in cultures in liquid mediums. This morphology is relatively constant, and there is not the tendency to the formation of thread-like and other aberrant forms which is exhibited by the influenza bacillus. H. pertussis is nonmotile and nonspore-forming, and the smooth form is encapsulated.

On the Bordet-Gengou medium the colonies are smooth, raised, and glistening, with a metallic or pearl-like luster, and are larger and more opaque than those of the influenza bacillus; 48 to 72 hours' incubation is required for their appearance and development. Upon further incubation they acquire a slight brownish color. A mucoid substance is abundantly produced by the culture, and the growth is sticky and tenacious. On blood agar the colonies are surrounded by a narrow zone of hazy hemolysis.

The bacilli stain with a little difficulty and, as in the case of the influenza bacillus, methylene blue or dilute carbol fuchsin must be applied for five to 10 minutes; carbol toluidine blue is recommended by some workers and stains the bacilli a lilac color. A tendency to bipolar staining may be observed. They are gram-negative.

Physiology. H. pertussis is difficult to cultivate upon primary isolation, and the Bordet-Gengou medium upon which it grows readily consists of 1 per cent glycerol agar on glycerol broth made with macerated potato and added to an equal volume of human or rabbit blood. By repeated passage on mediums containing less and less blood, however, it may be acclimatized and will, in time, grow, although sparsely, upon ordinary nutrient agar. It does not, therefore, require the V and X factors that are essential to the development of the hemophilic bacteria. The optimum temperature is 37° C., and the bacillus is aerobic and facultatively anaerobic.

Growth with the maintenance of immunogenic potency of phase I (see below) for vaccine production is a matter of practical importance. A number of casein hydrolysate mediums have been devised^{53, 55} for this purpose, and the inclusion of charcoal in beef heart agar tends to preserve immu-

PERTUSSIS 583

nogenic potency.³⁸ Starch is required in such mediums.

H. pertussis is biochemically inactive. It does not form indol, does not reduce nitrates, and does not ferment any sugars. Its resistance is slight and of the same order as that of the influenza bacillus. It is killed by exposure to 55° C. for 30 minutes.

Toxins. As in the case of Pfeiffer's bacillus, the cell substance of H. pertussis is toxic upon parenteral injection into experimental animals and to about the same degree. Endotoxin may be separated as a watery extract of disintegrated cells. There appear to be two fractions, one heat-stable and the other heat-labile and inactivated in 30 minutes at 56° C. On intravenous inoculation in rabbits the heat-stable fraction produces hyperglycemia and the heat-labile fraction hypoglycemia. Intratracheal inoculation in rabbits produces an edematous reaction followed by a lymphocytic infiltration about the blood vessels and bronchi which is reported to be similar to the changes produced in the lung in whooping cough. The endotoxin of a variant strain has been prepared by fractionation of sonic lysates⁵⁶ by extraction of lyophilized bacilli with calcium chloride, followed by methanol precipitation in the cold,47 and by ion exchange chromatography.5

Variation and antigenic structure. Unlike the influenza bacillus, H. pertussis is generally in the smooth state when isolated from the body on an optimal medium and is immunologically homogeneous; i.e., the virulent form occurs only as a single antigenic type,⁵⁴ phase I. Culture strains fall into four immunological groups which are designated phases I, II, III, and IV. Although not obviously rough, phases III and IV are somewhat rougher in appearance and less stable in saline suspensions than the bacilli of phase I. The S-R dissociation of H. pertussis occurs readily on culture on artificial mediums, even on blood agar, and it seems probable that these phases do not represent distinct immunological types but rather successive stages in the S-R transformation. As indicated above, virulence and immunogenicity may be maintained by cultivation on charcoal agar.43

The S-R change, of which the above phases represent the early stages, proceeds to the obviously rough state with consequent alterations in colonial morphology and loss of virulence.

As indicated elsewhere, H. pertussis is

immunologically related to Brucella bronchiseptica. Atypical bacilli isolated from a small proportion of cases of whooping cough have been designated H. parapertussis. These bacilli differ from H. pertussis in that they grow readily on ordinary nutrient agar upon isolation and produce an alkalinity in litmus milk in two to four days. Immunologically, they are related to both H. pertussis and Br. bronchiseptica through common O antigens, but are differentiated by capsular, or K, antigens.^{2, 28}

Pathogenicity for man.27,50 Whooping cough is widespread throughout the entire world, and it is estimated that 95 per cent of the population suffer from it, in typical or atypical form, at one time or another. The typical disease is commonest in the lower age groups and is much more serious in children than in adults. While the mortality has been steadily reduced, its relative importance as a cause of death under five years has increased progressively, and now it is exceeded in importance in this age group only by gastroenteritis, pneumonia and bronchitis, and tuberculosis. It occurs in three stages, each lasting about two weeks. The catarrhal stage begins with a mild cough that progresses in severity to a paroxysmal stage characterized by rapid consecutive coughs and the deep inspiratory whoop. In the convalescent stage the number and frequency of paroxysms gradually decrease, and recovery is uneventful except that bronchial and lobar pneumonia and otitis media occur with some frequency as complications, especially in children. The bacilli are present in large numbers in the respiratory tract in the catarrhal, and most contagious, stage, and gradually disappear until they are rarely found after the fourth week.

Although certain features of whooping cough may be approximately reproduced in experimental animals, the mechanism by which the microorganisms produce the disease in man is not altogether clear. The characteristic lymphocytosis and the leucocytic exudate into the lumen of the trachea and bronchi have been regarded as evidence of the activity of the endotoxins. The bacilli are also present in large numbers, especially in the catarrhal stage, between the cilia and possibly interfere mechanically with ciliary action. The localization of the bacteria and especially the persistence of the paroxysmal cough after the bacteria are no longer detectable, however, tend to set whooping cough somewhat apart from the other bac-

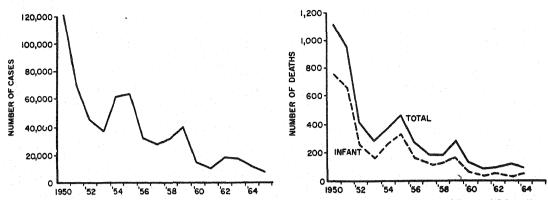

Figure 140. Pertussis cases and deaths reported in the United States, 1950-1965. (Morbidity and Mortality Weekly Report, Annual Supplement, Vol. 14, No. 53. Communicable Disease Center, Public Health Service, U. S. Department of Health, Education, and Welfare.)

terial respiratory infections. The observation that in the mouse either parenteral inoculation with vaccine or intranasal infection results in a remarkable increase in sensitivity to histamine (see below) suggests that some form of tissue sensitivity, of which increased histamine sensitivity may be a manifestation, plays a part in the pathogenesis of the disease.

Pathogenicity for animals. Naturally occurring infections of lower animals with H. pertussis do not occur and, in general, it is of variable and usually low virulence for experimental animals. The developing chick embryo may be infected, with reproduction of the cellular infiltration and necrosis of the bronchi seen at autopsy of fatal cases of the human disease,48 and the bacilli may be grown in tissue culture. 10 Both the rat and the mouse may be infected by intranasal inoculation to produce interstitial pneumonia with leucocytic infiltration around the vessels and bronchioles and mucous secretion on the bronchial epithelium.49 The mouse may be infected by intracerebral inoculation; smooth strains are the more virulent and the most virulent strains have an LD50 of 100 to 1000 bacilli by this route. Intracerebral infection of the mouse is used routinely in the standardization of the immunogenic potency of vaccines in this country; while it would appear to be quite unrelated to the human disease, Pittman⁴¹ has found that there is a reasonable correlation between virulence as tested by this method and by intranasal inoculation of the mouse.

Bacteriological diagnosis.³² The bacillus may be isolated by the cough plate method in which the open plate is held 4 to 5 inches

from the mouth and exposed to one or more explosive coughs. Nasopharyngeal swab cultures give a higher proportion of positive cultures than the cough-plate method, and the pernasal swab a higher proportion of positive cultures than the postnasal swab.³⁷ The swab, on thin, flexible, copper wire, is passed through a nostril into the nasopharvnx and left there for two or three coughs before withdrawal, and cultured on Bordet-Gengou medium. Sputum culture is not particularly satisfactory. Colonies of H. pertussis are larger and more opaque than those of the influenza bacillus; it may be differentiated further by hemolysis on blood agar and growth in the absence of the X and V factors.

Chemotherapy.^{25, 44} The chemotherapy of whooping cough is not as successful as that of many of the other infectious diseases, but the broad-spectrum antibiotics, chloramphenicol and the tetracyclines, have been found to reduce the duration and severity of the disease significantly in many instances, and occasional dramatic results have been reported. The sulfonamides and penicillin are ineffective.

Epidemiology.²² An upper respiratory infection, whooping cough is transmitted by means of the secretions of the mouth and nose, to some extent through towels, hand-kerchiefs, hand-to-hand contact, and the like, and undoubtedly to a great extent by droplet infection. Undiagnosed and atypical cases may play an important part in the dissemination of the disease. The age incidence is marked, with 96 per cent of the deaths in children under five years of age, and there is no doubt that whooping cough is one of

Carlo Distriction and accompanies of the control of

585

the most important killing diseases of childhood. There appears to be some racial difference in susceptibility, since the Negro death rate is considerably higher than that of the whites. In contrast to most other diseases the incidence in females is somewhat higher than that in males and in children in higher economic groups. The seasonal incidence shows a drop during late summer and early fall, with a prolonged peak in the later winter and spring. The disease tends to recur in periodic epidemic waves, presumably a consequence of the accumulation of a new crop of susceptibles.

Immunity. Recovery from whooping cough is accompanied by the development of immunity. Second attacks occur only infrequently in children and then are very mild; in older people second attacks are more severe. Complement-fixing antibodies are formed but do not appear until the third or fourth week of the disease and, consequently, are of limited diagnostic value.

Under experimental conditions are three kinds of response to the bacilli. There is a very rapid development, usually within a few hours, of a refractory state in which the animals are highly, and specifically, resistant to challenge inoculation, which persists for a week or more;^{17, 18} it is considered to be in the nature of an interference phenomenon. Second, as a consequence of inoculation with vaccine, or infection, mice become extremely sensitive to the action of histamine.29 Such sensitized animals show an enhanced susceptibility to anaphylaxis, a local cutaneous reaction as well as systemic anaphylaxis.30 Finally, the usual antibody response, with the presence of protective, complement-fixing, etc., antibody demonstrable in the serum occurs also. The protective antigen is separable from the toxin; it has been prepared in soluble form by partial deoxycholate lysis of the bacteria⁶ and purified from lysate by starch block electrophoresis.39 In the latter preparation the protective antigen and the histamine-sensitizing substance were not separable, although separation of the two has also been reported.13

Prophylactic inoculation. The early attempts to use vaccines of *H. pertussis* were not uniformly successful. More encouraging results were obtained by Madsen and other Danish bacteriologists in the Faroe Islands. In the United States Sauer and his colleagues have prepared vaccines

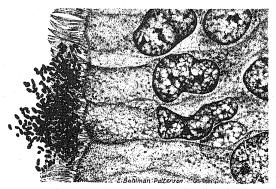

Figure 141. Whooping cough. Minute bacilli present in masses between cilia of two cells lining the trachea. About \times 1500.

of freshly isolated, virulent strains which appear to be effective in reducing the incidence and severity of the disease. It is of primary importance that the vaccine consist of the smooth bacilli of phase I, and earlier reports of the inefficacy of active immunization are probably attributable in part, at least, to the use of other than the smooth form of the microorganism. Immunogenic potency of vaccines requires constant assay and control: in the United States a standard test, using intracerebral challenge in the mouse, is used, and similar control procedures are used by others.3 Alum-precipitated vaccine seems to be effective also, but it is not known whether it is superior to plain vaccine.

Pertussis vaccine may be successfully combined with diphtheria toxoid and tetanus toxoid to allow immunization against the three diseases simultaneously; available evidence indicates that the immune response is equal to that obtained with separate antigens. In quadruple vaccines, containing inactivated poliomyelitis antigen also, the immunogenic potency of the pertussis component deteriorates, presumably as a consequence of the presence of a protease derived from the monkey kidney tissue used in the production of the poliovirus component. It is generally agreed that the disease is appreciably milder in immunized children.

With the demonstration of the endotoxins of *H. pertussis*, considerable interest has attached to the possible role of anti-endotoxin in immunity to the disease. The toxicity appears to be neutralized with appropriately prepared antiserum, and studies with experimental animals suggest that

antitoxic antibody may be significant in the immunity.

THE MORAX-AXENFELD DIPLOBACILLUS (HEMOPHILUS DUPLEX)

A small bacillus, described independently by Morax and by Axenfeld in 1896 and 1897, is responsible for infections of the conjunctiva and cornea in man and is known as the Morax-Axenfeld bacillus or *B. lacunatus* (from the lacunae of liquefaction produced by growth on coagulated serum). It has been grouped with the hemophilic bac-

teria as H. duplex.

The short rods, 1 μ by 2 to 3 μ , frequently appear end to end in pairs or short chains. They are nonmotile, nonspore-forming and gram-negative. They do not grow on the ordinary nutrient mediums, potato, milk, or gelatin but require the presence of serum, ascitic fluid, or blood in the culture medium. They ferment few if any carbohydrates and do not form indol. Coagulated serum is liquefied. They die out within a day or two at room temperature but may survive for weeks in culture in the incubator. It has been reported that hemolytic and nonhemolytic types occur which may be differentiated immunologically.

So far as is known this microorganism is pathogenic only for the human eye. The inoculation of experimental animals is without effect, but the instillation of the bacilli onto the conjunctival sac of man results in the development of blepharo-conjunctivitis, either chronic or acute, and severe inflammation of the cornea may be produced. Treatment with 0.25 per cent zinc sulfate solution is specific and produces a rapid cure, while silver salts are without effect.

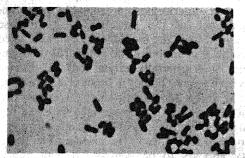

Figure 142. Hemophilus duplex (Morax-Axenfeld bacillus); pure culture. Gram stain; × 2400.

Chlortetracycline is reported to be highly effective when used as a 1 per cent ointment, and streptomycin is effective also. The disease is widely distributed and has been reported in Europe, Africa, and North America.

DUCREY'S BACILLUS (HEMOPHILUS DUCREYI)

Soft chancre or chancroid is a venereal disease transmitted by direct contact. The lesions, which are on the genitals or adjacent areas, are irregular ulcers which differ from the hard or Hunterian chancre—the primary lesion of syphilis—in that they are not indurated. Unlike syphilis, the infection remains localized, spreading no further than the neighboring lymphatics, which may become swollen to form secondary buboes in the groin.⁴

The bacillus was found by Ducrey in 1890 in the purulent discharge from the lesion, and by the inoculation of the skin of the forearm he was able to transmit the disease through 15 generations. The microorganism was obtained in pure culture by Besancon, Griffon, and le Sourd in the same

vear.

Ducrey's bacillus is a short rod 1 to 1.5 μ in length and 0.6 μ in breadth. In smears it is generally found to be ovoid, and there is a tendency to occur in end-to-end pairs or in short chains; in broth culture longer chains may be observed. It is nonspore-forming and nonmotile. The bacillus not infrequently stains irregularly and bipolar staining may be observed. It is stained by the usual aniline dyes and is gram-negative.

The bacillus will not grow on the ordinary laboratory mediums and requires the addition of serum or, preferably, blood.⁴⁵ The X and V factors alone are not sufficient, and additional factors present in either serum or erythrocytes are required. The small, grayish, glistening colonies appear in blood agar in 24 hours and, after two to three days' incubation, show a narrow zone of hemolysis. The bacilli may be cultivated from the chancroid by inoculating tubes of fresh (not more than three to five days old) rabbit blood. Smears made at the end of 24 to 48 hours' incubation will show the characteristic tangled chains of gram-negative bacilli. These bacteria cannot be identified

in smears from the chancroid because of a tendency to aberrant morphology. The bacilli may be isolated and cultivated on the chorioallantois of the developing chick embryo and appear to have little pathogenicity for the embryo. Rabbits and monkeys may be infected by intradermal inoculation of pure cultures, but subcutaneous, intraperitoneal, and intravenous inoculation is without effect. Infected animals develop a hypersensitivity but no immunity to reinfection. ¹².

There is little or no immunity. The chancroid is frequently multiple and is auto-inoculable. A hypersensitivity develops, which is demonstrable as a reaction to the intradermal inoculation of killed bacilli and which persists for many years. The disease may be successfully treated with the common drugs with the exception of penicillin; chlortetracycline is regarded by many as the drug of choice, and streptomycin has given excellent results.

Hemophilus vaginalis. Another hemophilic microorganism has been described as occurring in association with, and possibly in etiological relation to, human vaginitis.¹⁹ Like the other members of the group, H. vaginalis is a small, nonencapsulated, nonmotile gram-negative bacillus. It is somewhat more exacting in its nutritive requirements than the other Hemophilus species, is relatively inactive biochemically, and the delicate growth is facilitated by incubation in increased carbon dioxide tension.16, 46 Penicillin may be incorporated into the medium $(10\mu/\text{ml.})$ for primary isolation from contaminated specimens. It is reported to be clearly distinguishable serologically, by growth requirements, and by cultural characteristics.15

Chapter Twenty-seven

PSEUDOMONAS; LACTOBACILLUS; LISTERIA; ERYSIPELOTHRIX; BACTEROIDES; STREPTOBACILLUS; BARTONELLA; MYCOPLASMA; DONOVANIA

Pseudomonas aeruginosa (pyocyanea)

The genus Pseudomonas³⁹ includes some 30 species which are found, for the most part, in water, soil, and wherever organic matter is decomposing. The fluorescent bacteria are members of this genus, *Pseudomonas fluorescens* being the gelatin-liquefying form and *Ps. nonliquefaciens* the nonliquefying form. The elaboration of blue pigment by *Ps. syncyanea* results in "blue milk." One species, *Ps. septica*, is the cause of a disease of caterpillars, another, *Ps. reptilovorus*, produces disease in certain reptiles.

The best known species of Pseudomonas, however, and the only one that is pathogenic for man, is *Ps. aeruginosa*, which is also commonly known as *Ps. pyocyanea*. The blue or blue-green stains that sometimes appear upon surgical dressings long ago attracted attention, and even before the cause of the phenomenon had been discovered Fordos studied the pigment in 1860. Gessard found, in 1882, that the pigment was the product of a specific microorganism, *Ps. aeruginosa*, which he isolated in pure culture.

Morphology and staining. The cells of Ps. aeruginosa vary considerably in size and proportion but appear usually as small, slender rods, 1.5 to 3 μ long and 0.5 μ broad, frequently united in pairs and short chains. There are one to three polar flagella, and the

bacterium is actively motile. Neither capsules nor spores are formed. The colonies are large and spreading, the edges are irregular, and the consistency butyrous. The bacilli stain readily with the usual aniline dyes and are gram-negative.

Physiology. Ps. aeruginosa grows readily on all the ordinary culture mediums and most rapidly at a temperature of 30° to

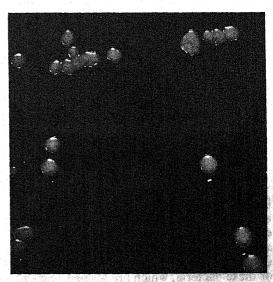

Figure 143. Colonies of *Pseudomonas fluorescens* on nutrient agar, 24-hour culture. × 3.

37° C. Aerobic conditions are required, although there is some growth under anaerobic conditions. Gelatin is rapidly liquefied, hydrogen sulfide is produced, and indol is not formed (false positives are sometimes given with Ehrlich's reagent, but not with Kovacs' reagent). The fermentative abilities of this bacterium are limited; acid is produced from dextrose, but most other carbohydrates are not attacked. An alkaline reaction is produced in litmus milk; a soft coagulum is formed, followed by rapid peptonization, and reduction of the indicator.

One of the most distinctive characteristics of Ps. aeruginosa is its production of a bluish green, soluble pigment which does not color the colonies or other masses of growth but instead diffuses into the medium. There are actually two pigments formed. The one, pyocyanin, is a deep blue in color and can be extracted from aqueous solution by chloroform, and the other, a yellowish green fluorescent pigment, is soluble in water but not in chloroform. They are both oxidation products of colorless precursors. Pyocyanin is formed only by Ps. aeruginosa, but the fluorescent pigment is formed by several other species of Pseudomonas.28 These pigments may occur separately or together. Pyocyanin is of interest in that it is a phenazine.

The serological character of Pseudomonas, especially *Ps. aeruginosa*, was open to question for many years. It is now established that there is antigenic diversity within the species with respect to both H and O antigens, allowing the differentiation of 10 O groups, which in combination with the 10 H antigens, has allowed the separation of 29 agglutinative serotypes. There appears to be no species-specific antigen, but the O antigens of *Ps. aeruginosa* seem not to occur in other Pseudomonas species. Strains

may be separated into a number of phage types, 49,54 but such typing has had little practical application as yet.

Pathogenicity. For some time after its discovery Ps. aeruginosa was generally regarded as a harmless saprophyte, or at the most as a microorganism of slight pathogenic power. It subsequently became clear that this bacterium is causally associated with a great variety of suppurative and other infections of man. It is found in pure culture in abscesses in different parts of the body. especially in the middle ear. 60 Cases of endocarditis,40 pneumonia, and meningitis,47 though rare, also occur in which Ps. aeruginosa appears to be the sole responsible microorganism. A generalized and fatal form of pyocyanic infection occurs, and the bacillus has been found in the blood during life.8 Ps. aeruginosa has beeen associated, possibly etiologically, with waterborne diarrheal disease.30

Infections with *Ps. aeruginosa* and other Pseudomonas species are difficult to treat because they do not respond well or uniformly to antibacterial drugs. In general, polymyxin is the most consistently active, streptomycin and the tetracyclines are less active and give variable results, and penicillin, erythromycin, and other antibiotics affecting the gram-positive bacteria have substantially no therapeutic effect.²

The intraperitoneal injection of 0.25 ml. of culture of a virulent strain will kill a guinea pig with acute symptoms in 24 hours. Smaller amounts are also fatal but less rapidly. Subcutaneous inoculation produces a marked local reaction. The symptom complex presents nothing especially characteristic. Rabbits are not so susceptible as guinea pigs; mice and pigeons are less susceptible than rabbits. Immunity can be produced by small, nonlethal doses.

Lactobacillus

Microorganisms comprising this somewhat loosely assembled genus produce considerable amounts of lactic acid from the simpler carbohydrates and concomitantly withstand a degree of acidity usually fatal to nonsporulating bacteria. This acid-tolerant attribute of these bacteria, which are termed aciduric, is extremely useful in the isolation of cultures as well as in distinguishing the group.

Morphologically some of the lactobacilli are long, slender rods, while others are somewhat similar to the colon bacillus, but, unlike it, they are all gram-positive. Almost all are nonmotile, but exceptions have been reported. Many cultures exhibit a typical diplobacillary form, often kidney-shaped. Old cultures frequently show considerable pleomorphism.

Physiology. The lactobacilli are microaerophilic or anaerobic on primary isolation. but after continued cultivation some strains will grow in the presence of air. Their nutritional requirements are complex, and most strains cannot be cultivated on the usual nutrient or infusion mediums unless these are enriched by the addition of glucose or whey. Individual requirements for amino acids vary from two to 15, and pyridoxine, thiamin, riboflavin, biotin, folic acid, and nicotinic acid are required in general, individual requirements differing. Such varied nutritional requirements have valuable practical application in microbiological assay procedures for vitamins and certain amino acids, for they are more sensitive than available chemical methods. Within an appropriate concentration range, there is a definite, even linear, relation between the concentration of vitamin in a vitamin-free but otherwise nutritionally adequate culture medium and the amount of growth or acid produced.

Some lactobacilli are a part of the normal intestinal flora and may predominate in infants and others having a high intake of sugars, especially lactose. At one time it was supposed that a lactobacillus intestinal flora was preferable to a coliform proteolytic flora because it tended to inhibit degenerative changes with increased vitality in the higher age groups, and that such a flora could be established by consumption of fermented milks, acidophilus and bulgaricus milks. The composition of the intestinal flora may be altered in this way, and also by the consumption of equal amounts of sweet milk, but the change is temporary, and in any case there is no evidence that such an intestinal flora in itself favors general health.

While rare instances of association of lactobacilli with pathological conditions, such as endocarditis and febrile disease, have been noted, these bacteria are essentially nonpathogenic except insofar as they may be associated with dental caries (see below). They are primarily of interest in the dairy and fermentation industries, where they are of considerable importance.

Classification. The classification of lactobacilli has been based on the source from which they were isolated. Such a basis is unsatisfactory except possibly in the case of certain obligate parasitic bacteria having highly pronounced host specificities. No other means of differentiation and characterization has been completely satisfactory and, although physiological properties vary widely from strain to strain, at the present time species of lactobacilli are separated on a physiological basis, using optimum growth temperatures, anaerobiasis, and certain sugar fermentations.

The lactobacilli fall into two groups on the basis of the products of sugar fermentation. The homofermentative group, which is the largest, converts the fermented sugar almost entirely to lactic acid, while the heterofermentative group is made up of the forms which produce considerable amounts of other products of fermentation, including carbon dioxide, ethanol, and acetic acid. According to the Bergey classification, these two groups are divided into species in the following way:

Homofermentative lactobacilli:

(A) having an optimum temperature of 37° to 60° C. or higher

(1) produce acid from lactose

- (a) having an optimum temperature of 37° to 45° C.
 - (i) produce l-lactic acid Lactobacillus caucasicus Lactobacillus lactis
 - (ii) produce dl- or d-lactic acid micro-aerophilic Lactobacillus helveticus Lactobacillus acidophilus
 - (iii) anaerobic in freshly isolated cultures Lactobacillus bifidus
- (b) having an optimum temperature of 45° to 62° C.

Lactobacillus bulgaricus Lactobacillus thermophilus

- (2) do not produce acid from lactose Lactobacillus delbrueckii
- (B) having an optimum temperature between 28° and
 - (1) produce optically active lactic acid (a) produce d-lactic acid

Lactobacillus casei (b) produce l-lactic acid

Lactobacillus leichmannii

(2) produce optically inactive lactic acid Lactobacillus plantarum

Heterofermentative lactobacilli:

(A) having an optimum temperature of 28° to 32° C. (1) ferment raffinose, sucrose, and lactose

Lactobacillus pastorianus Lactobacillus buchneri

(2) do not ferment raffinose, and often not sucrose or lactose

Lactobacillus brevis

(B) having an optimum temperature of 35° to 40° C. or higher

Lactobacillus fermenti

TO A POWER SHOW A SHOW A PARTY OF THE

A number of studies of the serological relationships among the lactobacilli have been

Figure 144. Lactobacillus sp. isolated from the mouth. Morphologically identical with L. acidophilus. Note the diplobacillary form and palisade arrangement of the cell. × 2500. (Harrison.)

carried out, using polysaccharides extracted from the bacteria as antigens, and the conventional agglutinin-agglutinin absorption methods. In the first instance, four serological types were separated but appeared to be somewhat unstable, changes in antigenicity being associated with changes in fermentation reactions.^{24, 25, 26} While the study of agglutinogens is complicated by the marked tendency of lactobacilli to spontaneous agglutination in salt solution, 10 different agglutinogens are demonstrable among the homofermentative lactobacilli, together with certain minor antigens shared with Leuconostoc species.^{44, 74, 75}

Of the lactobacillus species distinguished by physiological reactions, only three need be considered here.

by Moro in 1900 from the feces of infants, this organism has been isolated from the intestine of nearly all the mammalia, many other vertebrates, and some of the invertebrates. Its number increases in the intestine when the carbohydrate content of the diet is increased and may become predominant when a milk diet is ingested. These bacilli, fairly large and of variable length, are arranged singly, in pairs frequently slightly bent at the juncture, and in palisades. Long chains, filamentous forms, and club shapes are not uncommon. Young cultures stain

uniformly gram-positive; old cultures often show beading or bipolar staining and may be easily destained. Colonies, usually small, may vary in shape between a smooth, rounded. opaque form and a flattened, translucent, irregular form often having a ground-glass appearance. Fermentation reactions are variable, but most strains produce acid (no gas) from glucose, lactose, maltose, and sucrose and coagulate milk within 48 hours. Döderlein's bacillus (1892), a common constituent of the flora of the vagina and believed to aid in the natural defenses against infection by contributing to the acidity of the vaginal secretions, is considered to be identical with L. acidophilus.

Lactobacillus bifidus. Apparently closely related to L. acidophilus and often difficult to distinguish from it, L. bifidus is a thinner rod with ends somewhat more tapering and usually bifurcated on isolation. It was isolated from feces of breast-fed infants by Tissier in 1900. Although common in the intestine of breast-fed infants, sometimes comprising over 90 per cent of the total intestinal flora, it is less conspicuous in the intestinal contents of bottle-fed babies. It is sometimes found also in the feces of adult animals, including man. Like L. acidophilus it produces acid, mainly lactic, from a number of sugars but also ferments inulin. It is anaerobic on primary isolation, and some strains never grow well under aerobic conditions. Growth is enhanced by cystine. Partly because of its anaerobic requirements it has been classified with the Bacteroides.

Lactobacillus bulgaricus. This name was assigned to an organism isolated by Grigoroff in 1905 from Bulgarian fermented milk. It gained prominence through the work of Metchnikoff, who believed that intestinal putrefaction could be restrained by drinking milk fermented by this organism as noted above. When it was later shown that L. bulgaricus does not become implanted in the intestine, its use in experimental therapeusis was dropped in favor of L. acidophilus. More difficult to cultivate than L. acidophilus, slightly larger, and somewhat different in sugar fermentations, it is nevertheless closely related. It has been reported that L. bulgaricus rarely grows at 15° C., dies out on repeated culture in a lactose-peptoneyeast extract broth, is unable to grow in mediums containing 2.5 per cent sodium chloride, and fails to grow in broth at pH

a**li lina ka Macaminina da P**ilipa ka manga berjag

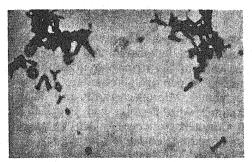

Figure 145. Lactobacillus bifidus. Note the Y-shaped forms. (Dack.)

7.8, while *L. acidophilus* will grow under all these conditions. The Boas-Oppler bacillus, first seen in 1895 in the gastric juice of patients suffering from stomach carcinoma, is a member of this group, similar to if not identical with *L. bulgaricus*.

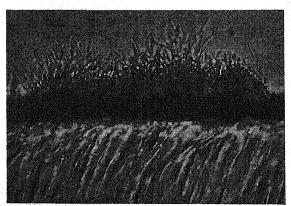

Dental caries. 66 Decalcification of the tooth, which is a prominent part of dental caries, may be brought about by organic acids of microbial origin. Acid formation occurs rapidly in dental plaques (see below) as measured by microelectrodes following oral rinse with glucose solution, reaching concentrations sufficient for decalcification in vitro. The lactobacilli are not only constantly present in the mouth and induce a rapid conversion of carbohydrate to lactic acid, but their aciduric nature allows their persistence in such acidities. It has been sus-

pected, therefore, that they may be etiologically related to the carious process.

The mouth contains a wide variety of bacteria, such as streptococci, filamentous forms, bacteroides, and spirochetes, in addition to lactobacilli. The composition of the flora is affected by the nature of the diet, including dietary deficiencies, and by other factors such as antibiotic therapy, which often results in a predominantly coliform flora. It is also significantly altered when certain pathological conditions are present in the mouth, and such alterations may reflect any part played, particularly by those forms which increase in number, in the pathological process.

In general, gingivitis and periodontal disease are associated with a predominantly proteolytic flora. Involvement of the gum margins may range from mild involvement of the buccal and lingual margins and interdental papillae to the acute or chronic ulceromembranous gingivitis known as Vincent's disease. The classic microscopic picture of spirochetes and fusiform bacilli diagnostic of Vincent's angina (Chap. Thirty-three) is incomplete in that a variety of other forms may be found in the masses of bacteria growing along the gingival margin.

The carious lesion is commonly initiated beneath a tooth plaque, a felt-like mass on the surface of the tooth made up of filamentous microorganisms in which various kinds of bacteria are entrapped. The predominant forms are α -hemolytic streptococci, gram-

atili ladi aktorografi i komuni

594

positive diplococci, diphtheroid bacilli, and anaerobic fusiform bacilli, together with smaller numbers of lactobacilli. Neisseria. and other gram-negative cocci. It has been found generally, though not invariably, that the number of lactobacilli present in the saliva increases during active caries, and that both the development of the carious process and the increase in number of lactobacilli are arrested by sharp restriction of sugars in the diet. Such observations have been taken to suggest a role of the lactobacillus flora in the decalcification of caries, and there would seem to be little doubt that bacteria are causally involved, since experimental caries does not occur in germ-free animals.45

More recent evidence, based on studies with germ-free animals and animals in which portions of the bacterial flora have been depressed with antibiotics, have cast doubt on a role being played by the lactobacilli in the initiation of the carious process: these studies have tended to implicate certain kinds, or strains, of streptococci.31 It will be recalled that the streptococci, like the lactobacilli, are distinguished by the fermentation of glucose primarily to lactic acid, and the Streptococceae and Lactobacilleae are the two tribes making up the family Lactobacillaceae. In addition, the streptococci are also proteolytic, and proteolysis is involved also in the development of caries. Whether there is a specific etiology of dental caries, or whether the carious process results from the activity of more than one kind of bacteria as seems to be the case in periodontal disease, remains to be established, but it seems probable that certain streptococci, and possibly also lactobacilli because of their aciduric nature, are significant elements.

RELATED BACTERIA

Microbacterium. Forms which are closely related to the lactobacilli and produce lactic acid without gas in carbohydrate fermentation, but which are aerobic, are grouped in the genus Microbacterium and formally classified with Listeria and Erysipelothrix as Corynebacteriaceae. Two species are recognized, Microbacterium lacticum and M. flavum. The first occurs in the intestinal tract, and the second predominantly in dairy products. Their relatively high heat resistance is of significance in the latter.

Propionic acid bacteria. A group of bacteria closely related to the lactobacilli, but characterized by the production of propionic acid and acetic acid in the fermentation of carbohydrates and polyhydric alcohols, is known as the propionic acid bacteria. The original single species, Bacterium acidi propionici, has been split into a number of species on a physiological basis under the generic name Propionibacterium. Of the 11 species recognized by Bergey all but one are anaerobic or micro-aerophilic.

They are nonmotile, nonspore-forming, gram-positive bacilli somewhat resembling the diphtheroids in microscopic morphology in that they contain metachromatic granules, and the cells are often club-shaped and show branching. Growth is relatively slow, and their nutritional requirements are complex in that yeast extract mediums supplemented with lactate or monosaccharides are required to support growth. These bacteria are of some industrial importance and have been widely used in studies on the mechanisms of bacterial fermentation of sugars. They seem to be completely nonpathogenic.

Listeria monocytogenes^{22, 61}

The microorganism now known as Listeria monocytogenes has undoubtedly been isolated from diseased lower animals and man prior to 1926, but without sufficiently precise characterization to allow its identification. In that year it was described by Murray, Webb, and Swann as the etiologic agent of an epizootic among laboratory rabbits and guinea pigs which was characterized in part by a monocytosis, and it was named by them Bacterium monocytogenes. What proved to be the same microorganism was isolated the following year by Pirie from the gerbil

(Tatera lobengulae) in South Africa, and named by him Listerella hepatolytica because of the lesions produced in the liver in experimentally infected animals. When the identity of these isolates was established, the microorganism was given the name Listerella monocytogenes. Following the objection of systematists that the generic name Listerella had been pre-empted, the name was changed to Listeria monocytogenes, by which it continues to be known despite further objections by systematists that this generic name had also been pre-empted. It

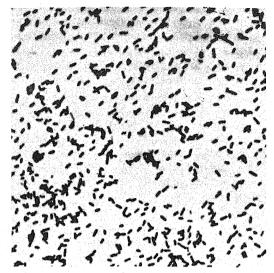

Figure 147. Listeria monocytogenes. Smear from a pure culture. Fuchsin: × 1050.

has been isolated since, but not recognized owing to insufficiently critical characterization, and the names Corynebacterium infantisepticum and Corynebacterium parvulum occur in the literature.

Morphology and staining. This microorganism is a nonsporulating, nonencapsulated rod with slightly pointed ends. In very young cultures it is found in bacillary form, but later it is predominantly coccoid, $0.5 \mu \times 1$ to 2μ , the form in which it is usually observed. In old cultures or cultures of the rough form, filaments 6 to 20 μ in length occur. The arrangement of the cells is not characteristic; they may be found singly, in pairs sometimes at an acute angle to one another, and in short chains.

In young cultures the bacilli are invariably gram-positive, but as the culture ages the Gram reaction becomes irregular. On partial decolorization as observed in older cultures, the center portion of the cell is decolorized first to suggest bipolar staining, but metachromatic granules and the banded appearance characteristic of the corvnebacteria does not occur. Some of the conventional simple stains, e.g., methylene blue, are not satisfactory, and the Gram stain or Giemsa should be used, especially for tissue sections.

These bacteria are motile, a characteristic which, among others, distinguishes them from Erysipelothrix (with which they are classified by British workers as Erysipelothrix monocytogenes), and motility is demonstrable by swarming in soft agar culture at 20° C. as well as by direct observation. When grown at room temperature there are four or less peritrichous flagella, but when cultured at 37° C. usually only a single polar flagellum is demonstrable.

Growth is diffuse in liquid media, except in the case of rough strains, and on solid media, e.g., tryptose, blood, or serum agar, minute opaque colonies appear in 24 to 48 hours, becoming larger with raised edges on continued incubation. There is a very small zone of \(\beta\)-hemolysis; occasional strains show much greater hemolytic activity on sheep blood agar which is correlated with lecithinase activity of the strain. Two main types of variants are found, the one more translucent and less hemolytic which is agglutinable in saline but retains antigenicity, and the other typically rough.

Physiology. These bacteria are grown, especially on primary isolation, on relatively rich mediums and under increased CO₂ tension. Growth occurs at neutral or slightly alkaline reactions, and these bacteria are unusual in their ability to grow well at pH's as high as 9.6 and in the presence of 10 per cent, or even more, NaCl. Growth is relatively slow in liquid mediums in the absence of fermentable carbohydrate, and may be delayed for one to two weeks or not occur at all when the inoculum is small; this may account for some failures to isolate Listeria from pathological material. When fermentable carbohydrate, e.g., glucose, is included in the medium, growth is much more rapid but, as the pH falls to 5.6 or less, the bacteria die out in two to three days. Enrichment occurs when the specimen is allowed to stand for one to three months in the refrigerator, owing presumably to the ability of these bacteria to grow slowly at such low temperatures, and subsequent subculture may be successful when immediate culture was not. They may be grown on defined mediums containing a number of amino acids.15

These bacteria are relatively inactive biochemically; i.e., they are not proteolytic, do not produce indole or H₂S, and fail to hydrolyze urea or reduce nitrates. Dextrose, maltose, levulose, salicin, and trehalose are almost invariably fermented but without gas formation; sucrose, lactose, glycerol, xylose, and rhamnose are fermented irregularly or only by some strains; and mannitol, dulcitol, arabinose, inositol, and raffinose are not fermented. The separation

596

LISTERIA

of Listeria into fermentative types has not been useful.

With the exception of the enhanced hemolytic activity associated with lecithinase and the irregular fermentation of some carbohydrates, *List. monocytogenes* is remarkably uniform regardless of source. It is generally agreed, therefore, that there is but one species, and various names arising from presumed host specificity, such as *List. ovis, List. cuniculi, List. bovina, List. gerbilli,* and *List. gallinarum,* have no standing.

Antigenic structure.3 Earlier studies on the antigenic specificity of List. monocytogenes indicated that these microorganisms fall into two general serological types, types 1 and 4 below. One of these appeared to occur in rodents, the other in ruminants, and both in man. More precise studies, based on detailed antigenic analysis, have shown that both heat-labile flagellar and heat-stable somatic antigens are present. These allow differentiation of four main serotypes, designated 1, 2, 3, and 4, and the subdivision into subtypes of which type 4a and type 4b appear to be the most important. The antigenic structure of these serotypes is shown in the accompanying table. While List. monocytogenes may be identified and typed by the use of appropriate antiserums, crossreactions have been found to occur with a number of other bacteria, including strains of Str. fecalis, Staph. aureus, E. coli, and various Corynebacterium species. The serodiagnosis of Listeria infection using paired

serums from patients is, then, not reliable, for rise in titer to Listeria antigen may occur in infections with other microorganisms.

Toxins. The characteristic monocytosis, to as high as 30 per cent of the total white cell count by the fourth day of experimental infection in rabbits, is doubtless due, at least in large part, to the presence of a monocytosis-producing agent in the microorganisms. This is apparently a lipid substance, liberated by mechanical disruption of the cells and extractable with organic solvents such as chloroform, ether, or petroleum ether. The activity is correlated with virulence, for it is present in large amount in freshly isolated virulent strains, decreases rapidly coincident with decline in virulence on serial culture on laboratory mediums, and may be restored by animal passage. The partially purified material produces an effect on the hematopoietic system substantially identical with that which occurs in experimental infection, but it does not appear to be otherwise toxic. Whether polysaccharide fractions of the bacilli are toxic as has been reported has not been established. A protein substance, separable from mechanically disrupted cells and precipitable by ammonium sulfate, has been reported to have a virulence-enhancing effect.48 These bacteria appear to have no endotoxin in the conventional sense.

Pathogenicity. Naturally occurring infection of lower animals and man, or lisapparently world-wide teriosis. is distribution though most of the reported cases have been in this country and Western Europe. There have been several thousand confirmed infections in lower animals, particularly domestic animals, and more than 700 confirmed human cases have been recorded. It is probable that many are missed because the disease cannot be diagnosed with certainty on clinical grounds alone, and because of failure to isolate and/or recognize the microorganism.

In lower animals the disease occurs in both sporadic and epizootic form. It assumes a generalized septicemic form in rodents and in young animals generally, with the development of necrotic foci in the liver. In older animals there is a tendency to involvement of the central nervous system with resulting encephalitis or encephalomyelitis. The infection also has a tendency to localize in the reproductive system, resulting in abortion in pregnant animals. Among domes-

tic animals the sheep appears to be among the most susceptible, and the disease takes a fulminating form with high mortality, at times assuming considerable economic importance. The disease is known as "circling disease" in these animals, but relevant symptoms of central nervous system infection are not invariably present. Cattle are infected also, and swine less often; the horse is infected only occasionally. Epizootics have occurred in colonies of furbearing animals such as foxes and chinchillas.

Of the common experimental animals³³, the mouse and rabbit appear to be among the most susceptible, and fatal infection is readily produced by intravenous or intraperitoneal inoculation. The guinea pig is less susceptible and cannot be fatally infected with regularity. Freshly isolated smooth strains of *List. monocytogenes* appear to be almost invariably highly virulent, and test for virulence is a significant element in its characterization, but, since virulence is lost readily on culture on laboratory mediums, it may appear to differ widely from strain to strain when culture strains are tested.

Listeriosis in man may be a localized infection, cutaneous or of mucous membranes of varying severity to give upper respiratory symptoms, angina, involvement of regional lymphatics, and at times associated conjunctivitis. Monocytosis is common in this kind of infection. Or it may assume, or progress to, a generalized septicemic form with infection of the reproductive system and transplacental transmission to the fetus in pregnant women, or neonatal infection or involve the central nervous system with resulting encephalitis. Histologically the lesions are granulomas and focal necroses. Diagnosis cannot be based on symptomatology; the septic form with angina and monocytosis is indistinguishable from infectious mononucleosis of viral or other etiology (Chap. Thirty-seven), the encephalitis, in which monocytosis is not a constant feature, does not differ significantly from encephalitis of other bacterial or viral etiology, etc. The case fatality rate appears to be high, perhaps 70 per cent when the central nervous system is involved. At the same time, asymptomatic and abortive infections occur, but their relative frequency is not known. Tetracyclines and sulfonamides are considered to be reasonably effective chemotherapeutic agents if given early; penicillin is apparently not consistently effective. The microorganism may be isolated from the blood, or bone marrow by sternal puncture, early in the disease; from purulent material taken from lymph nodes and cutaneous lesions; from swab specimens of infected mucous membranes; and from spinal fluid when the central nervous system is infected.

Epidemiology.²¹ The epidemiology listeriosis is as yet far from clear. It is considered to be primarily a disease of lower animals, possibly with a reservoir of infection in rodents as suggested by the isolation of the microorganisms from such animals in the wild state. Nevertheless, it has been possible in only relatively few instances of confirmed infection to trace the source of infection. Among domestic animals an association with certain feeds, especially silage, has been noted by many workers, and List. monocytogenes has, in fact, been isolated directly from silage. The source of contamination of silage is another matter, and a saprophytic stage in the life history of the microorganism cannot be ruled out. It is probable that human infection is acquired from lower animals through direct or indirect contact. With the exception of transplacental infection of the human fetus, or neonatal infection acquired at birth, the disease seems not to be transmitted from man to man.

Erysipelothrix rhusiopathiae 76

Microorganisms closely related to the actinomycetes have been found to be the causative agents of swine erysipelas and a type of mouse septicemia; they also infect man, and the disease produced is termed erysipeloid to distinguish it from erysipelas of streptococcal etiology. It was thought

for a time that the mouse septicemia organism isolated by Koch, the organism isolated from swine by Pasteur and Thuillier and by Löffler, and that found by Rosenbach in human erysipeloid were distinct species of a genus to which the name Erysipelothrix has been given, and they were called Ery-

sipelothrix muriseptica, Ery. rhusiopathiae, and Ery. erysipeloides respectively. The first of these, sometimes called Bact, murisepticum, is not to be confused with Pasteurella muriseptica, which also has the same synonym. Other names that have been used are Ery. rhusiopathiae suis, Ery. porci, erysipelatis suis, Actinomyces Bacillus rhusiopathiae, and the swine rotlauf bacillus. It is now generally agreed that these organisms are identical, or at least closely related varieties of the same species, for while their morphology is variable they are immunologically identical and are recognized as a single species, Ery. rhusiopathiae. These microorganisms are regarded by some workers as related to L. monocytogenes.

Morphology and physiology.64 Ery. rhusiopathiae occurs in two rather well defined morphological types usually designated smooth and rough though their relationship to the S and R variants of bacterial dissociation is not clear. The smooth type appears as a small, slender, sometimes slightly curved, nonmotile, nonsporulating, grampositive rod. Long chains of bacilli and filaments, sometimes beaded and showing swollen areas, are present in smears of the rough form. Both stain readily and sometimes irregularly with deeply staining granules. Colonies of the smooth form on solid mediums are round, convex, amorphous, water-clear, and small, perhaps 0.1 mm. in diameter, and broth cultures are uniformly turbid. The rough form produces larger colonies with a granular, curled appearance like that of very small colonies of anthrax bacilli, while growth in liquid mediums is in the form of flocculent, hair-like masses with little or no turbidity. The most characteristic growth is in gelatin stab cultures; bead-like colonies appear along the line of inoculation from which lateral filamentous growth occurs, resembling a test-tube brush.

The organism is micro-aerophilic but will grow under aerobic or anaerobic conditions; growth appears on the usual infusion mediums with 24 hours' incubation at the optimum temperature of 30° C. There is no growth on potato. Fermentation reactions are variable from strain to strain, but most ferment dextrose, lactose, and levulose. Nitrate is reduced and hydrogen sulfide is produced, but indol is not formed, and litmus milk is unchanged or slightly acidified.

Ery. rhusiopathiae is somewhat more

than ordinarily resistant to drying and to various preservative processes such as smoking, pickling, and salting and survives for relatively long periods in putrefying meat and in water. It is probably in part because of survival of the organisms in filth that infected areas experience recurrences of the disease year after year.

Pathogenicity. In swine, four clinical types of disease are found. In the acute septicemic form, with lesions in the viscera and internal organs, the case fatality rate is high, perhaps 80 per cent, with death in three to five days. The urticarial form, known as "diamonds" or "diamond skin disease" because of the occurrence of reddish to purplish rhomboidal blotches on the skin, may occur with or without visceral involvement and is seldom fatal. The chronic form is a vegetative endocarditis with erosion of the mitral valves in particular; death always results eventually. Arthritis may complicate the other clinical types or occur independently; it is usually not fatal, but growth is stunted. The organisms are excreted in large numbers in the feces, and it is generally assumed that natural infection takes place by mouth although experimental feeding has given irregular results. Infection is spread in part by healthy carriers as well as diseased animals, and pork trimmings in garbage probably account for isolated cases. Swine erysipelas is of very great economic importance in Europe, especially in Germany where it is known as Schweinerotlauf, and in recent years has been found to be

Figure 148. Erysipelothrix rhusiopathiae, pure culture. Note the similarity of this microorganism to the actinomycetes. × 1000. (Kral.)

LISTERIOSIS 599

more important in this country, at least in certain areas, than formerly thought.

Sheep are occasionally infected with Ery. rhusiopathiae and develop a polyarthritic form of the disease. The organism is also pathogenic for a variety of birds, and in this country turkeys are most often seriously affected; cyanosis is a prominent clinical feature and evident in the "blue comb." It has also been found in wild rats, which should, perhaps, be considered as a reservoir of infection and possibly a source of the human disease.

The disease may be reproduced by the inoculation of swine, though the results are irregular. Of the usual laboratory animals, white mice and pigeons are highly susceptible, dying in one to four days after subcutaneous inoculation, and are commonly used in diagnosis. The rabbit is not very susceptible, and the guinea pig is quite resistant. In general, the virulence of the microorganism varies widely.

Pathogenicity for man.34,56 Human infection with Ery. rhusiopathiae is well known. The septicemic type with diffuse erythema is rare in man, and only a very few instances have been reported. The chronic form with endocarditis and polyarthritis is also very rare. The usual type of infection is an erythematous-edematous lesion, the local lesion commonly developing on the fingers or hand from an abrasion where the infection enters. The lesion, although spreading, never extends beyond the wrist. There is some swelling and a marked erythema of the lesion and sometimes local arthritis and regional adenitis. The disease is usually self-limiting and terminates within a month. The organism may be cultivated from an excised piece of skin from the lesion.

Human infection can almost invariably be traced to contact with animals and animal products such as meat, hides, bones, and manure, or to fish and shellfish, and the disease is, therefore, associated with certain occupations.³⁵ For example, more than half the cases found in the Philadelphia

region were in slaughterhouse workers. The disease has been observed in workers in a bone button factory using cattle and hog bones, and it not uncommon in fishermen and fish handlers. It also occurs in persons working in kitchens with raw meat and fish. In this country, contact with live fish and crustacea appears to be the chief source of infection. Hettche has reported finding Ery. rhusiopathiae in 10 of 30 specimens of sewage at Königsberg in Prussia and in five of 52 specimens at Munich; the source apparently was slaughterhouses where infected animals were being killed. Under experimental conditions the organisms not only survived for some days in water, but fish developed a latent infection when fed infected meat; the microorganism could be isolated from most organs, including the kidney, and were excreted in large numbers in the urine, contaminating the water.

Immunity. There is a definite immune response in infected hogs as evidenced by the formation of agglutinins which have diagnostic value. Ery. rhusiopathiae is immunologically relatively homogeneous, but serological groups may be distinguished^{32,72} by reciprocal absorption. Antiserum has therapeutic value, and in man is given both intramuscularly and by infiltration about the local lesion. Passive immunization of swine is an effective prophylactic but the immunity lasts no longer than two weeks. Animals may be actively immunized with the vaccine developed by Pasteur and Thuillier, who attenuated the organism by passing it through rabbits. Vaccine erysipelas occurs with some frequency, however, and the method has now been largely superseded by the simultaneous inoculation of virulent culture and antiserum. Since the vaccine maintains and spreads infection in herds, the Bureau of Animal Industry has permitted only its limited use in this country and only in areas where the disease has become prevalent. Both methods provide adequate protection for eight to 12 months; periodic reimmunization is required for breeding stock.

Nonspore-forming Anaerobic Bacilli (Bacteroides)

There is a large group of nonspore-forming anaerobic bacilli that are usually gramnegative. Normal inhabitants of the upper respiratory tract, genital tract, and colon, where they may outnumber the aerobic flora, 78 the microorganisms are not infre-

quently associated with ulcerative processes of the mucous membranes and may, under appropriate circumstances, invade the tissues and organs of the body with the production of abscesses, or the blood stream to give rise to septicemia.^{4, 14, 68} Generally

neglected in routine bacteriological examinations, these bacteria may be present in "sterile pus" from surgically drained abscesses and similar affections in which bacteria are not found by the usual cultural methods. Dack⁹ noted their presence in 200 of 5180 specimens from the Department of Surgery of the University of Chicago submitted for routine bacteriological examination, an incidence of about 4 per cent.

The relation of these microorganisms to other bacteria is uncertain. As a group they probably make up several genera and cannot be regarded as species of a single genus except tentatively. They are morphologically heterogeneous, varying from slender rod forms which may be tapered toward the ends, the so-called fusiform bacilli, to filamentous and branching forms characteristic of the higher fungi. The high degree of pleomorphism characteristic of these forms is due in large part to a mode of reproduction in which large round bodies are formed from which daughter cells separate. These usually resemble the bacillary parent cells but sometimes occur as much smaller elements in the so-called L type of variation. 63

Single species have been given a variety of generic names, including Bacillus, Bacterium, Necrobacillus, Bacterioides, Corynebacterium, Streptothrix, and Actinomyces. Descriptions of these bacteria have been compiled and Prevot⁵⁵ has suggested a more or less elaborate classification.

The Bergey classification separates these forms into two familes and eight genera (exclusive of Streptobacillus) on a morphological basis, viz.:

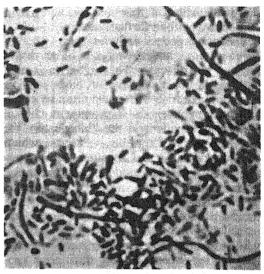

Figure 149. Bacteroides funduliformis. The swollen and filamentous forms and poorly staining "ghost cells" are typical of the usual stained smear preparations. × 1000. (Dack.)

Bacteroidaceae

Bacterioides (rounded ends)

Fusobacterium (pointed ends)

Dialister (minute, diameter of 150 m μ or less)

Sphaerophorus (pleomorphic)

Lactobacillaceae

Lactobacilleae

Eubacterium (no filaments)

Catenabacterium (filaments)

Ramibacterium (false branching)

Cillobacterium (motile)

The difficulty is that the characteristic of failure to form spores and that of requiring anaerobic conditions for growth cover an otherwise heterogeneous group of micro-

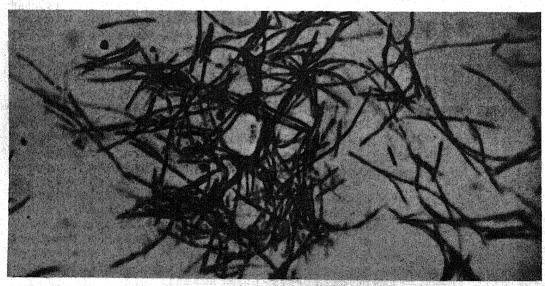

Figure 150. Fusiform bacilli in a stained smear from an anaerobic blood agar culture. × 1800. (Hemmens.)

organisms, not only these but also anaerobic streptococci, Viellonella, etc., most of which are poorly known, both in their relation to one another and to other microorganisms. In view of this, they will, for present purposes, be discussed here under the single name Bacteroides without generic implication in the taxonomic sense.

Those forms which are present in great numbers in normal feces will grow upon the usual laboratory mediums. Those which are associated with pathological processes in man, however, are nutritively fastidious and require infusion mediums enriched by the addition of blood, yeast, or vegetable extracts, and similar substances, together with glucose and cysteine. In some cases they may be isolated on beef or veal infusion blood agar. Some strains grow in amino acid mediums supplemented with all the known bacterial vitamins; pyruvic acid appears to be of considerable importance in the nutrition of these organisms. The optimum pH is 6.3 to 7.0, and the optimum temperature for growth is 37° C. Completely anaerobic conditions are essential, and growth is favored by the presence of carbon dioxide. In vitro they are sensitive to tetracycline and chloramphenicol, but are resistant to streptomycin as well as penicillin.65

The better known of these bacteria may be described briefly.

Bacteroides fusiformis (Bacillus fusiformis, Fusiformis fusiformis, Fusiformis fusiformis, Fusobacterium plauti-vincenti). These fusiform bacilli are found in ulcerative stomatitis (trench mouth) and Vincent's angina. Their relation to the spirochetes with which they are usually associated is considered above and elsewhere (Chap. Thirty-three). They appear as slender rectilinear or incurving

bacilli and frequently assume a filamentous form. They are gram-negative and tend to stain irregularly with the ordinary aniline dyes. Acid but no gas is produced from dextrose, levulose, sucrose, maltose, and sometimes from lactose. They may be isolated on blood agar incubated anaerobically, and the colonies are small and surrounded by a zone of green hemolysis. *Bacteroides fusiformis* is not pathogenic for experimental animals in pure culture, but in mixed culture produces abscesses.

Bacteroides fragilis (Bacillus fragilis, Fusiformis fragilis). This bacterium was found by Veillon and Zuber in 22 cases of appendicitis and since has been found in lung, pelvic, and hepatic abscesses, in septicemia with metastatic abscesses, and in infections of the urinary tract. The cells are small, slender rods, sometimes slightly curved. They are gram-negative and nonmotile. Bact. fragilis is difficult to isolate but will grow on the usual laboratory mediums. The colonies are small (less than 1 mm.) and transparent. No hemolysis is apparent on blood agar. There is a marked tendency to autolysis with apparent resorption of the colonies, and broth cultures are no longer viable after seven to eight days' incubation. A variety of sugars are fermented to acid and gas. The pathogenicity of this bacterium for experimental animals is uncertain.

Bacteroides funduliformis (Actinomyces necrophorus, Fusiformis necrophorus, Streptothrix necrophorus, Bacillus necrophorus, Corynebacterium necrophorum, Schmorl's bacillus). These bacilli have been found in abscesses of the liver, lung, and other parts of the body, in chronic ulcerative colitis, and in the blood stream. Infec-

Figure 151. Bacteroides funduliformis. Electron micrographs. Right, a pair of cells resulting from simple fission. Fixed in formalin; × 3300. Left, swollen cells containing granular material, especially in the swollen areas. Fixed in formalin; × 4900. (Smith, Mudd, and Hillier. 63)

tions with these microorganisms are probably more common than is generally realized. Bact. funduliformis has also been found in lower animals, as in bovine liver abscesses. The bacilli are highly pleomorphic; slender straight and curved rods may be found intermingled with filamentous and swollen forms, and "ghost cells" which do not stain are frequent. There is a marked tendency to irregular staining, and the bacilli are gramnegative. The colonies on blood agar are variable in size from plate to plate and surrounded by a zone of green hemolysis which may become clear upon prolonged exposure to the air. Glucose, maltose, and levulose are fermented to acid, and there is no evidence of proteolytic activity in gelatin or coagulated egg-white cultures. Some strains give rise to a spreading necrotic lesion upon subcutaneous injection in the rabbit, which is usually fatal, while others produce only a localized lesion. Guinea pigs are relatively resistant.

Bacteroides ramosus (Fusiformis mosus, Ramibacterium ramosum, Bacillus ramosus. Not to be confused with Bacillus ramosus as sometimes applied to Bacillus mycoides). These bacteria are frequently present in the pus of appendicitis and have been encountered in pulmonary gangrene. They appear as small, slender rods which often show branching Y forms and pseudofilaments. They are gram-positive. Bact. ramosus is pathogenic for experimental animals, giving rise to abscesses in rabbits and guinea pigs on subcutaneous injection; fatal infections are produced by intravenous inoculation.

Bacteroides melaninogenicus (Ristella melaninogenica). This microorganism has been found in the mouth, tonsils, infected abdominal wounds, focal infections of the

kidneys, in stools from patients with chronic amebic dysentery, and in puerperal sepsis. It is described as a very small gram-negative diplobacillus. On blood agar its colonies are black owing to the slow (four to five days) formation of a melanin-like pigment. Bact. melaninogenicus grows well in mixed culture but sparsely in pure culture. It is difficult to obtain in pure culture and, when admixed with other bacteria in a colony, colors the entire colony black. Acid is formed from dextrose, levulose, lactose, maltose, sucrose, and mannitol. It is markedly proteolytic and rapidly digests coagulated serum and other native proteins. Its pathogenicity as a primary invader is uncertain.

Bacteroides pneumosintes (Dialister pneumosintes). Bact. pneumosintes was described by Olitsky and Gates as the causal agent of influenza. Now known to bear no relation to this disease, its pathogenicity for man is uncertain. It may be cultured from nasopharyngeal washings in Smith-Noguchi medium (human ascitic fluid containing a piece of sterile rabbit kidney and covered with a petrolatum seal) and after a few transfers will grow anaerobically on blood agar, chocolate agar, and Bodet's medium. These bacteria are minute bodies arranged singly. in pairs, or in short chains; they are nonmotile and gram-negative. Because of their small size they pass Berkefeld V and N filters. They produce acid but no gas from dextrose; other sugars are not fermented. If mass cultures are injected intratracheally into rabbits, there is a rise in temperature and sometimes conjunctivitis and mononuclear leucopenia with recovery in two or three days. If the animal is sacrificed, the lungs are found to be edematous with hemorrhages on the surfaces. Bact. pneumosintes is not pathogenic for monkeys.

Streptobacillus moniliformis (Rat-bite Fever, Haverhill Fever)

A microorganism variously known as Streptothrix muris-ratti, Haverhillia multiformis, Streptobacillus moniliformis, Actinomyces muris, and A. muris-ratti is the cause of an acute febrile disease sometimes given the descriptive name erythema multiforme. It is also called rat-bite fever because it may be acquired through the bite of infected rats.

For a good many years the etiology of the disease known as rat-bite fever was con-

fused, for Schottmüller, Blake, and others isolated from the blood of patients a fungus to which the name Streptothrix muris-ratti was given, while Japanese work indicated that a similar disease, known in Japan as sodoku, is caused by a spirochete. In 1925 an epidemic, milkborne disease with unusual and distinctive clinical features occurred in Haverhill, Massachusetts, and was given the descriptive name erythema arthriticum epidemicum or Haverhill fever by Place,

Paritrial instru

Sutton, and Willner.⁵³ The causative microorganism was isolated by Parker and Hudson;⁴⁶ it proved to be a member of the Actinomycetaceae and was given the provisional name *Haverhillia multiformis*. In the same year Levaditi³⁸ independently studied a similar organism from a case clinically like Haverhill fever and named it *Streptobacillus moniliformis*. Other work has yielded similar results. The Japanese work has also been amply confirmed, and it is now clear that there are two types of rat-bite fever, completely different in etiology.

The microorganism is, like the other actinomycetes, pleomorphic in culture with filaments fragmented, branching lary and coccobacillary forms being found in stained smears. Staining may be irregular, and swollen and club-shaped cells are found. It has been suggested that this organism is related to the organisms of the pleuropneumonia group. It is not acid-fast and is gramnegative. It requires enriched mediums for growth; Parker and Hudson found whole rabbit blood, allowed to clot and then inactivated, and broth containing serum or ascitic fluid excellent liquid mediums, and glycerin extract of potato, mixed with infusion broth, enriched with egg yolk, and coagulated by inspissation, the best solid medium. Löffler's serum medium is not particularly satisfactory. Growth is markedly better under anaerobic conditions in the presence of added carbon dioxide than in

When the disease in man is contracted through a rat bite, the initial wound heals, but after a week or 10 days becomes inflamed and painful. Adenitis develops and is followed by toxic symptoms which are the first evidence of the disease acquired from milk. These include headache, chills,

vomiting, and general malaise. An eruption of morbilliform character appears, especially on the extremities, and there is multiple arthritis, often severe. The clinical resemblance to rat-bite fever of spirochetal etiology is very close. The causative microorganism may be isolated by blood culture and has been found in the fluid of affected joints. Agglutinins are formed and according to Brown and Nunemaker⁵ are of considerable diagnostic utility.

S. moniliformis has been found to be a normal parasite of rats and mice and is present in the nasopharynx. It may assume pathogenicity for the rodent host and produce sporadic or epidemic disease of either an acute septicemic or chronic polyarthritic type. An epizootic of the latter type in wild mice has been reported from Australia. The organism has also been found in bronchopneumonia of rats. Although usually of low virulence on artificial inoculation in rats, an experimental infection has been produced with one strain that gives an osteoarthritis.³⁷ It is clear that man may acquire the disease by the bite of normal rats, and probably almost all sporadic cases arise in this way. Brown and Nunemaker are of the opinion that rat bite produces the streptobacillus infection much more commonly than the spirochete infection in this country. The number of undiagnosed cases and the proportion of previously reported cases of rat-bite fever that were S. moniliformis infections are not known. As indicated above, the Haverhill epidemic was milkborne; another milkborne outbreak involving 86 persons was reported in 1934. Parker and Hudson found evidence which suggested that the Haverhill milk was contaminated by an infected cow, but this could not be proved: others have suggested contamination of milk by rats as a possibility.

Bartonella

Bartonella bacilliformis. Oroya fever, an infectious anemia, and verruga peruana, a disease characterized by miliary or nodular eruptions, have existed for centuries in certain districts in Peru and recently have been found in Colombia and Ecuador. It was shown by Carrión, through fatal selfinoculation, that the two are stages or manifestations of a single disease which is now commonly known as Carrión's disease. The etiological agent is a small pleomorphic ba-

cillus which was observed by Barton in 1905 and named *Bartonella bacilliformis* by Strong, Tyzzer, and Sellards.

Morphology and staining.⁵² Bart. bacilliformis is a small, motile, aerobic, gramnegative bacillus 0.2 to 0.5 μ in diameter and 1 to 2 μ in length which is found as a slightly curved rod occurring singly, end to end in pairs, and in short chains. A rounded ovoid form, 0.3 to 1 μ in diameter, is also observed singly, in pairs, and in groups. It

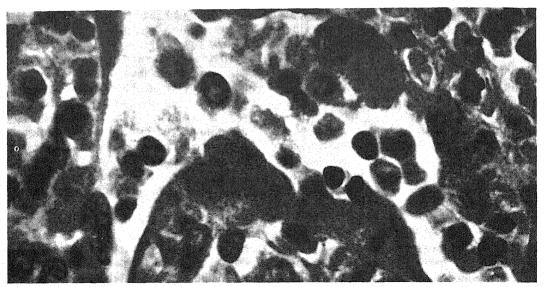

Figure 152. Bartonella bacilliformis in human spleen. Note the huge numbers of the microorganisms packed into the lining cells. Giemsa; × 1450. (Humphreys.)

stains reddish violet with Giemsa's stain, sometimes showing a reddish purple granule at one end of a bluish rod.

Physiology. This microorganism was first cultivated in semisolid leptospira medium and later in tissue culture and in the developing chick embryo, though it could not be carried in serial transfer in the last. Sparse growth occurs on cystine-dextrose-blood agar, and apparently the X factor is required while the V factor is not. Gieman¹⁶ has developed a tryptone-serum medium in both liquid and solid form which supports excellent growth. Little is known of its physiological processes.

Pathogenicity for man. 59 As indicated above, the disease occurs in two forms: the systemic form, in which the red cells are infected; and the histoid cutaneous form. The two may exist independently, coexist, or occur separately, though the usual course is the systemic form followed by the cutaneous form if the former is not fatal, or the cutaneous form alone. The first is a severe. often fatal, febrile anemia. The incubation period is given as about three weeks. The anemia is frequently severe, and the loss of red cells may be 200,000 to 300,000 per cu. mm. per day until the total count is half a million or less. The anemia is thought to be due to the direct action of the microorganisms on the erythrocytes, including hemolysis, and to tissue hemorrhages.⁵⁸ The fever is of an irregular remittent type, and pain in the bones, joints, and head is common. The case fatality rate is 20 to 40 per cent.

death occurring in two to three weeks after onset. With recovery the eruptive stage of the disease appears and persists for two to three months. Whether it follows the systemic form or is the primary clinical manifestation of infection, this stage is characterized by a miliary or nodular eruption; the former is by far the more common. The miliary eruption is most common on the face and extremities, appearing as a macule which becomes nodular and eventually disappears leaving no scar. The nodular type of eruption develops more slowly; the nodules may become 2 to 3 cm. in diameter and have a tendency to become strangulated. They are formed by the proliferation of the endothelial cells of the vessels which become obstructed with an inflammatory exudate of plasma cells and fibroblasts and show a marked tendency to hemorrhage.

Bartonella cells are found in large numbers within the erythrocytes in Orova fever and may be demonstrated in Giemsa-stained blood smears. In both forms of the disease they are found in the tissue macrophages, especially the vascular endothelial cells of the lymphatics, spleen, and liver, often in large clusters within individual cells. The infection is frequently complicated by Salmonella infection to give a high mortality.⁷ It is reported that blood cultures are frequently positive in the systemic infection. but it is not clear whether this is a reliable method of diagnosis. The disease has been treated successfully with chloramphenicol and tetracycline. 50, 69, 77 MYCOPLASMA 605

Bartonellosis is strictly Epidemiology. limited geographically, being, so far as is known, exclusively American and tropical. occurring in the Andes between latitudes 2° N. and 13° S. It is transmitted by Phlebotomus verrucarum and P. noguchii in Peru: whether other species of Phlebotomus or other arthropods, such as Dermacentor. are natural vectors is not known. Peruvian ground squirrels (Citellus tridecemlineatus) have been infected experimentally29 and, together with domestic animals, including chickens, and guinea pigs and field mice, may possibly be naturally infected. Whether there is such an animal reservoir of infection. or the disease is maintained in human infections only, is not known.

Immunity. It is generally said that recovery from an attack of either form of the disease confers a solid immunity to both. With the cultivation of Bart. bacilliformis, it has been possible to study the occurrence of circulating antibody, agglutinins, and investigate the possibilities of prophylactic inoculation. Agglutinins may be demonstrated during the early stages of the disease but, in spite of the lasting immunity, almost always disappear with the subsidence of clinical symptoms. Their diagnostic significance is not as vet known.

Pathogenicity for animals. In general experimental animals appear to be highly resistant to infection with Bart. bacilliformis. Both the eruptive and systemic forms of the disease have been produced in rhesus monkeys, the latter form in splenectomized animals.

Bartonellosis of animals. Naturally occurring bartonellosis has been found in a number of animals, including the dog, cattle, and a variety of rodents. The infection takes a systemic rather than eruptive form and is usually latent, but is activated when host resistance is reduced as by splenectomy. The bartonella-like organisms of lower animals have been separated into three genera: Haemobartonella; Grahamella, containing but a single species (Grahamella talpae) which differs from Haemobartonella in that

the infection is not eradicated by treatment with arsenicals; and Eperythrozoon, which is more highly pleomorphic than the first two groups and is found in the plasma as well as in the erythrocytes. None of these forms has been cultivated, and all appear to be nonpathogenic for man.

Of these, the most commonly encountered is Haemobartonella muris, which infects rats and is transmitted by the rat louse. Haematopinus, and the rat flea, Xenopsylla cheopsis. The infection is very common, and the great majority of laboratory rats are infected. The infection is latent and may be precipitated in an acute form by splenectomy with the appearance of parasitized red cells in the circulating blood. Special strains of rats are maintained bartonella-free for experimental purposes. H. canis is the cause of an infectious anemia of dogs and is transmitted by the dog flea, Ctenocephalus. H. tyzzeri occurs in guinea pigs. H. microtii in the vole, H. bovis in cattle, and other species in mice, shrews, and squirrels.

Eperythrozoonosis similarly occurs as a latent infection which is activated by splenectomy. Eperythrozoon coccoides is a parasite of white mice, and other species occur in wild mice. The disease also occurs in sheep and cattle, and the causative organisms are E. ovis and E. wenyonii respectively.

The systemic position of Bartonella. relationship of these microorganisms to the bacteria on the one hand and to the rickettsiae and viruses on the other is of some interest. Among the bacteria the tendency to parasitize the cells of the host and appear as intracellular clumps of microorganisms is most marked in Past. tularensis, which commonly is found in an intracellular position. Bartonella shows a much more marked preference for intracellular parasitism, and both in this respect and in morphology seems to be closely related to the rickettsiae. It is generally agreed, however, that the relationship is not sufficiently close to justify their classification as rickettsiae, and they may be considered as lying between them and the bacteria.

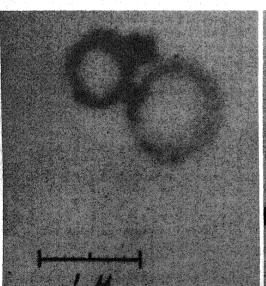

Mycoplasma — The Pleuropneumonia-like Organisms (PPLO)¹²

The first of an apparently more or less homogeneous group of highly pleomorphic, filtrable microorganisms to be described is the causative agent of bovine pleuropneumonia. Subsequently a number of similar forms, both parasitic and saprophytic, have been found. They have been called the pleuropneumonia group or pleuropneumonialike organisms, though none of the rest produces pleuropneumonia in cattle. They are set rather sharply apart from other microorganisms, and are considered to fall into a single genus, Mycoplasma, and the bovine pleuropneumonia organism is taken to be the type species, Mycoplasma mycoides.¹³

Morphology and staining. 11, 71 There are probably few if any other microorganisms which are as highly pleomorphic as these forms. Impression preparations of colonies show granules of various sizes, filaments which may be branched and contain streaming protoplasm, balloon and disc-like structures, ring, club, and star forms, and ameboid structures. Filaments are more numerous in recently isolated cultures and tend not to be formed in older stock cultures. The microscopic morphology of these forms is illustrated in the accompanying figures. The marked pleomorphism is due in part to the fragility of the organisms, many of which are torn apart in making smears, and, as in the case of Bact. funduliformis, in part a consequence of modes of reproduction other than binary fission, e.g., that of the development of round bodies which become nodular with outgrowths that segment into daughter cells. This process has been studied in detail by means of electron micrographs. Viable structures vary greatly in size and include ultramicroscopic elements which are filtrable. Experiments on filtration through gradocol membranes have been described in which the concentration of organisms in an emulsion was reduced from 10^8 to 10^5 by passage through a membrane of APD 0.8 μ . This titer decreased progressively with membranes of decreasing pore size, but complete retention did not occur until a membrane of 0.33 μ was used. In contrast to this, the end point is usually sharp in the filtration of viruses. On the basis of these observations the diameter of the smallest viable elements was estimated to be 165 to 247 m μ . Similar estimates vary somewhat for other strains; the agent of pleuropneumonia, for example, is 125 to 175 m μ .

These forms cannot be found in tissues by any method of staining. They are not demonstrable in smears stained by the usual aniline dyes, but are stained by certain polychrome stains, Giemsa, and Castaneda's rickettsia stain. Very thick films prepared from the sediment of centrifuged cultures are gramnegative.

On primary isolation or change to a slightly different culture medium, broth cultures sometimes, but not always, show no detectable evidence of growth and may be carried along by "blind passage" for several transfers before it appears. Some strains show a uniform opalescence, others a granular type of growth. The characteristic of some strains to grow as small colonies, appearing as flakes attached to the side of the tube, is of some differential value. In any case, visible evidence of growth is very slight, and almost

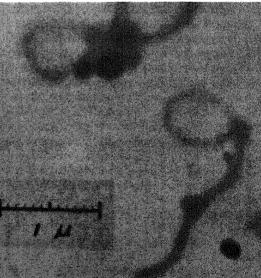

Figure 153. Electron micrographs of the ring forms of the pleuropneumonia-like organisms. (Lilly Research Laboratories.)

all workers with these organisms have found it necessary to carry along an uninoculated tube of medium for comparative purposes.

The colonies upon an agar surface are usually not detectable until after two or three days' incubation. They are most readily observed in stained agar preparations. A square of agar is cut from a suspicious area on the plate and placed on a slide. It is covered with a cover slip on which an alcoholic solution of methylene blue and azure has been dried, and the space between the cover slip and the slide filled with melted paraffin. The average colony size of different strains ranges from 0.01 to 0.6 mm., rarely exceeding the larger figure. The colonies usually have a dark center with a lighter margin and may appear coarsely or finely granular. Upon higher magnification a foamlike structure may be observed which is composed of the balloon-like forms. Oily droplets may be found in the colonies of some strains; these have been found, in some cases at least, to be largely cholesterol already present in the medium. Possibly the pseudocolonies which have been observed on uninoculated serum agar are of similar nature; it is said that these are readily differentiated from true colonies by experienced observers.

Physiology.^{1, 62} These microorganisms require infusion or digest mediums enriched by the addition of serum or ascitic fluid in relatively large amounts. Their growth requirements, especially on primary isolation, have been studied by Morton and his coworkers.^{41, 42} They have shown that these microorganisms are regularly cultivable on a beef heart infusion medium at pH 7.8, containing Bacto peptone or Parke, Davis bac-

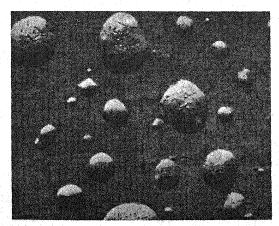

Figure 154. Colonies of a type B pleuropneumonialike organism from mice. Three days' incubation. \times 100. (Sabin: Bacteriol. Rev.)

teriological peptone, and enriched with a heat-stable factor present in ascitic fluid and serum. In some cases these organisms tolerate a relatively wide pH range, but others die out at pH 7.0 and below, and require a pH of 7.8 to 8.0 for growth. The saprophytic varieties will grow at 22° C. with an optimum at 30° C., but the parasitic ones require 37° C. Growth occurs both aerobically and anaerobically but is less abundant in most strains under anaerobic conditions. Fairly heavy inoculums are required, 0.1 to 0.2 ml. of minced tissue in primary isolation, with the transfer of similar amounts of broth cultures, and in transfer from agar cultures a small section of the medium is cut out and dropped into liquid mediums or streaked on another plate. Curiously, their primary isolation is, as a rule, accomplished more readily than their maintenance. These organisms may also be cultured on the chorioallantoic membrane of the developing hen's egg. They are also cultivable in tissue culture, but do not produce a cytopathic effect; their presence in tissue cultures, grossly inapparent, may complicate the use of such substrates for the cultivation of animal viruses.

Some sugars, notably glucose, are fermented, but the pH seldom drops below 7.0 owing to the death of the organisms at this point; the addition of other sugars may inhibit growth. In general, fermentations and other biochemical characteristics have no differential value. The heat resistance of some strains is of the same order as that of most bacteria, while others appear to be more frail and are killed by exposure to 45° C. for 15 minutes. Cultures are best preserved at incubator temperature in mediums containing no added sugar; when sealed with petrolatum the organism may remain viable for a month or more.

Varieties, strains, or species. Strains of these organisms have been isolated from a variety of sources. Those which are parasitic are definitely set off from the saprophytic types, and differentiation or identification within these groups has been made in part on source and pathogenicity and in part on an immunological (agglutination) basis.

With the study of bacterial protoplasts and their similarities to both the L forms of bacteria and the pleuropneumonia-like organisms (PPLO), and the association of the last two with one another (see below), the existence of the PPLO as a group of independent entities becomes uncertain. It has

been urged by a number of workers, especially Dienes, that the PPLO represent stages in the life history of microorganisms better known in other forms. Although there is no convincing evidence that an orderly, cyclical transformation of morphological types occurs among bacteria in this sense (Chap. Seven), at the same time the possibility that the PPLO are naturally occurring protoplasts, differing from the parent microorganism only in lacking a cell wall structure, is highly suggestive. While, then, the PPLO are considered to be independent entities, and given the generic name Mycoplasma in a separate order Mycoplasmatales, any attempt to do other than describe these forms, their origin, and the pathological conditions with which they have been associated seems premature.

Bovine pleuropneumonia. As indicated above, the causative organism of pleuropneumonia of cattle was the first of these forms to be isolated and studied. The disease is found all over the world except in India. Western Europe, and North America; it has been imported into this country a number of times but was finally eradicated by the slaughter of infected animals and has not occurred since 1892.

The natural disease in cattle is characterized by extensive consolidation and subpleural effusion in either or both lungs, and the microorganism is present in large numbers in the serous exudate. It spreads slowly in herds and may take an acute form with death within a week or a chronic form with walling off of the foci of infection. There is occasional joint involvement in young animals. The natural disease has not been reproduced in cattle by either inoculation of infectious serous exudate or of cultures, but an extensive edema develops and spreads from the site of inoculation, and there is a febrile reaction and sometimes death.

The organism is apparently completely nonpathogenic for the usual experimental animals and for man; it has been reported that cultures in sheep- or horse-serum mediums are infectious for sheep and goats, while those in bovine-serum mediums are not.

The name Asterococcus mycoides was given the organism by Borrel and Dujardin-Beaumetz but has not been generally used. In any case, strains obtained in different localities and at different times appear to be very similar if not identical.

Contagious agalactia of sheep and goats. Despite its name this disease is a generalized infection which affects both males and females. It occurs only in parts of southern Europe and North Africa; agalactia or mastitis of these animals in this country is of other etiology.

The lesions occur in the joints and eyes and in the mammary glands of females. The microorganism is present in the blood early in the disease and later may be isolated from the affected regions and from the mammary secretions. The second member of the group to be studied, it was isolated by Bridré and Donatien in 1923. It is morphologically and biochemically very similar to the pleuropneumonia organism and other members of the group but is immunologically distinct and of characteristic pathogenicity. The disease is readily reproduced by inoculation of sheep and goats with cultures.

Canine variety. Organisms of the pleuropneumonia group have also been found in dogs. Shoetensak reported in 1934 the cultivation of an organism of this type from the purulent nasal discharge of dogs ill with distemper which he called Asterococcus canis. In later studies other organisms were found, and there appeared to be two types, immunologically distinct from one another, which he called type I and type II respectively. Their postulated etiological relationship to distemper, generally regarded as a virus disease, is not established.

Varieties from rats. A series of pleuropneumonia-like organisms has been isolated by Klieneberger and her associates from the respiratory tract and elsewhere in normal and diseased rats. Others have isolated similar organisms from rats exhibiting polyarthritis and swollen extremities. These comprise, with a single exception, the "L" series of strains in which the strains are designated by subscript numerals. There now appear to be three distinct types, differentiated on a biological and immunological basis, viz., L_1 , L_3 , and L_4 . The strain L_2 was isolated from a guinea pig and insufficiently studied before loss of the culture at the outbreak of war. The strain described as L₅ is immunologically identical with mouse type A discussed below; L₆ has been insufficiently studied; and L7 has been found to be identical with L₄.

Considerable interest has attached to the apparent association of L₁ with S. moniliformis. Klieneberger-Nobel has been able to isolate L_1 from many strains and stock cultures of S. moniliformis, and it will be recalled that this organism is a natural parasite of the nasopharynx of rats and mice. It is maintained by Klieneberger-Nobel that L_1 and streptobacillus coexist as symbionts, since she has been able to separate the two on the basis of differential resistance to heat and aging, has observed L_1 in the rat in the absence of S. moniliformis, and has carried L_1 strains through many transplants without its reappearance.

These L forms are associated, causally in some instances at least, with relatively mild, chronic affections of rats in which a not uncommon manifestation is joint involvement and polyarthritis. They closely resemble the other organisms of the group morphologically and culturally, forming a subgroup on the basis of pathogenicity, and differentiated from one another immunolog-

ically.

Varieties from mice. Sabin divides the pleuropneumonia-like organisms found in mice into five types, designated as A, B, C, D, and E. Type A is found in normal mice, once in the brain and frequently in the eyes, nasal mucosa, and lungs of carriers. On intracerebral inoculation of mice an ataxia is produced which is characterized by a turning or rolling of the body. The brain lesions and symptoms arising from them are attributable to the action of a soluble toxin produced by the microorganisms.67 immunologically identical organism was isolated by Findlay et al. from mice affected with "rolling disease" and designated L₅. Type B has likewise been found in normal mice and is not only immunologically distinct but produces a progressive arthritis almost exclusively when parenterally inoculated into mice. Types C, D, and E are similar in their pathogenicity but are immunologically distinct; they have not been studied as extensively as some of the others.

Saprophytic varieties. Pleuropneumonialike organisms presumably living a saprophytic existence in nature have been found by Laidlaw and Elford in raw London sewage. They closely resembled the parasitic forms both morphologically and culturally and fell into three immunological groups which were designated types A, B, and C. All were nonpathogenic for experimental animals. Similar forms have been found in Germany in compost and other types of decomposing organic matter.

MYCOPLASMA OF MAN²⁷

Within the past few years interest in Mycoplasma has been greatly stimulated by the demonstration of the etiological relation of one kind of these agents to human pneumonia. A number of species, or strains, differentiable from one another largely, though not entirely, on an immunological basis have been defined. These include M. hominis, types 1 and 2, and M. fermentans, found in the genitourinary tract; M. salivarium and M. orale (M. pharyngis), occurring in the upper respiratory tract; and M. pneumoniae, the causal agent of primary atypical pneumonia. Other varieties have been isolated from the urogenital tract which are as yet poorly characterized, and are known collectively as the T strains.

Primary atypical pneumonia.6 During the 1940's the disease known as primary atypical pneumonia, or PAP, was characterized as a clinical entity, but it became increasingly apparent that this seeming entity may be of diverse etiology. In some instances the causal agent is the psittacosis agent, in others adenoviruses and in still others the disease may be caused by such diverse microorganisms as Histoplasma, Coccioides, or the Q fever rickettsiae. A portion of the cases of PAP is, however, set apart by the appearance of cold hemagglutinin in the serum which agglutinates homologous or type O human cells at 4° C. but not at 37° C., and an agglutinin for the MG strain of nonhemolytic streptococcus (Chap. Seventeen).

This disease was studied by Eaton and his associates, who cultured the causative agent in the chick embryo and produced pneumonia in cotton rats and hamsters by intranasal inoculation. This causative agent was considered to be a virus and was known as the Eaton agent. This microorganism appears to be an important cause of PAP, being responsible for as much as 90 per cent of the cases of the disease showing cold agglutinin. It has been found repeatedly in all parts of the country and elsewhere. and its prevalence is indicated by serological evidence of infection in undiagnosed lower respiratory infection. It was not until 1957 that the original strain was studied further, and additional, immunologically identical strains were repeatedly isolated. By means of the fluorescent antibody technique, it was shown that, following inoculation into

the amnionic cavity of 13-day embryonated eggs, the agent multiplied exclusively in the cytoplasm of the epithelial cells lining the bronchioles and air sacs of the developing embryo. It was found also that the disease may be treated effectively with tetracycline, but not penicillin. In 1962 the agent was cultivated on lifeless mediums and shown to be a Mycoplasma. The microorganism is immunologically homogeneous and has been designated M. pneumoniae. The suggestion that M. pneumoniae is an L form of the MG streptococcus⁵¹ was, perhaps, inevitable, but is not generally accepted; so far as is known the appearance of streptococcal agglutinin is fortuitous.

M. pneumoniae tends to be set apart from the other Mycoplasma in that it grows relatively slowly, forming granular colonies similar to those of M. fermentans, and in that it produces a hemolysin. It will grow in the presence of dilute (0.002 per cent) methylene blue and reduces triphenyl tetra-

zolium to give a pink discoloration,³⁶ characteristics which allow the development of selective isolation mediums.

Other infections. Mycoplasma have been associated with a number of other diseases of man, especially nongonococcal urethritis (Chap. Nineteen) in which M. hominis type 1 has been found repeatedly in large numbers. Various species have been found in conjunction with exudative pharyngitis and tonsillitis, and the former condition has been produced in human volunteers with M. hominis type 1.43 In view of the arthritis of rats and mice produced by Mycoplasma, an association with arthritis in man has been considered, but these microorganisms have been found only occasionally in arthritic synovial fluid, and the condition is not suppurative as it is in rodents. The pathogenicity of Mycoplasma, other than M. pneumoniae, for man remains uncertain as vet, although the observed associations are suggestive.

Donovania granulomatis 57

The disease granuloma inguinale (granuloma venereum) is not to be confused with lymphogranuloma inguinale of virus etiology. It is characterized by a slowly progressive ulceration in the genital region and rarely elsewhere. The initial lesion is a swelling, often in the groin as a bubo, which ruptures. Daughter lesions appear which are at first discrete and then spread slowly and coalesce, and the process may eventually involve the skin of the groin, genitals, buttocks, and lower abdomen, and the patient develops a strong fetid odor. Little effective immunity appears to be developed, at least not sufficient to appreciably arrest the progress of the infection.

Bacillary bodies, stained by Wright's stain, were observed by Donovan in 1905 in smears from lesions or in biopsy material, and have long been known as Donovan bodies. They may also be stained with 1 per cent pinacyanole in methanol, the capsules assuming a purplish pink color and the cell body a dark blue color. The Donovan body has been cultivated in the yolk sac, but not on the chorioallantois, of the developing chick embryo and in enriched mediums such as beef heart infusion²³ and is thus shown to be a cultivable microorganism to which the

name *Donovania granulomatis* has been given. 18, 19

It is a short, plump bacillus 1.5 to 4.5 μ in length and 0.8 to 1.4 μ in breadth, gramnegative, and showing prominent polar granules. Prior to cell division the elongated bacillary forms tend to become curved and may remain attached after division to give rise to chains of bacilli, the coiled filaments often seen in the usual stained preparations. The relatively heavy encapsulation observed in preparations from lesion material and the mucoid character of volk sac cultures and initial cultures on artificial mediums diminish with continued culture. Aside from its highly fastidious growth requirements, D. granulomatis closely resembles Friedländer's bacillus and has been found to be closely related immunologically to this bacterium and to other coliform bacilli. There are antigenic differences between strains, complicating the problem of serodiagnosis, as by complement fixation. 17, 20

Prior to the isolation in pure culture of *D. granulomatis*, its causal relation to granuloma inguinale was only suggested by association. Material from yolk sac cultures gives a skin reaction in persons having the disease, and a mucoid substance from in-

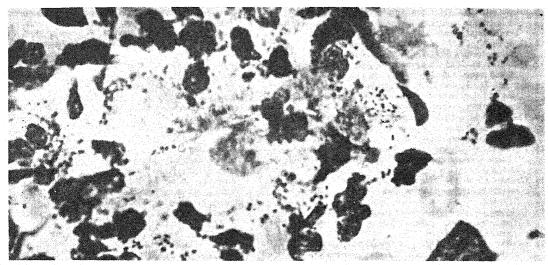

Figure 155. Donovania granulomatis in a waginal smear. The microorganisms are the small ovoid bodies both within polymorphonuclear leucocytes and lying free. Wright's stain; × 1200.

fected yolk sac, possibly a polysaccharide, gives precipitin and complement fixation reactions with serums from patients. The specificity of these reactions is, however, open to question in that apparently specific complement fixation was given by persons with chronic nonspecific ulceration perhaps attributable to the serological relation of D. granulomatis to coliform bacilli. Greenblatt and his co-workers were able to produce the disease in two human volunteers, one inoculated by a subcutaneous transplant of biopsy material and the other by the subcutaneous inoculation of yolk sac culture, but later were unable to repeat these results.¹⁰ Since it has not yet been possible to infect experimental animals other than the chick embryo, the etiological relation of D. granulomatis to granuloma inguinale cannot be regarded as fully established. Successful chemotherapy of the disease with chloramphenicol and tetracyclines has, however, been reported.

The general tendency to regard this disease as venereal is based in large part on the location of the lesions. There is little or no direct evidence that it is transmitted primarily by sexual contact and, in fact, its occurrence in both marital partners is uncommon. The probable incubation period of one to four weeks is not excessively long and should not greatly obscure histories of contact. It has been suggested that there is great individual variation in susceptibility and that natural resistance is usually of a

high order. The disease is associated with uncleanliness and is found in the Far East, Africa, and the Americas. In this country it occurs for the most part in the Negro of low economic status in the southeastern states, but it occurs elsewhere also. It is estimated that there are 5000 to 10,000 cases in the United States, and it has been found to constitute 2 to 3 per cent of venereal disease in Negro recruits. In general, however, the epidemiology of granuloma inguinale is as yet very poorly understood.

Chapter Twenty-eight

BACILLUS—THE SPORE-FORMING AEROBES

The spore-forming rod-shaped bacteria are divided into two groups on the basis of their relation to atmospheric oxygen. The genus Bacillus includes the aerobic forms, and the anaerobic types are designated Clostridium. A very large number of species of Bacillus have been described, the majority of them from soil and dust. Two species, Bacillus alvei and B. para-alvei, cause foul brood, a disease of bees. B. subtilis infects human beings only rarely, and, with this exception, B. anthracis is the only member of this large group that is pathogenic for man.

BACILLUS ANTHRACIS

Primarily a disease of lower animals transmissible to man, anthrax is of particular historical interest, for it was in his study of this disease that Koch provided the first demonstration of the causal relation between a specific bacterium and an infectious disease. The bacillus had been observed in the blood and organs of animals dving of anthrax by Davaine and Rayer in 1850 and by Pollender in 1855. In 1857 Brauell transmitted the disease by the inoculation of blood from infected animals. Conclusive demonstration of the causal relation between the bacilli and the disease, however, was the work of Koch, who in 1877 cultured the bacillus on the aqueous humor of the ox's eye, described its life history, and reproduced the disease with a pure culture of the microorganism. The importance of this discovery to the development of bacteriology has been discussed elsewhere.

Morphology and staining. The anthrax

bacillus is one of the largest of the pathogenic bacteria and ranges from 4.5 to $10~\mu$ in length and 1 to $1.25~\mu$ in breadth. The ends of the rods are often concave and somewhat swollen so that the appearance of a chain of anthrax bacilli has been compared to a jointed bamboo fishing rod. The cells occur singly and as end-to-end pairs or short chains in the body, but in culture long chains are formed. Unlike most of the sporulating aerobic bacilli they are nonmotile.

Capsules may be found on the bacilli in smears from an infected animal but are not found in culture except on mediums rich in animal protein, such as serum agar. The capsular material is not polysaccharide as it is in most bacteria, but is a high molecular weight polypeptide composed exclusively of d(-) glutamic acid (the "unnatural" 29.53 stereoisomer). This is a point of particular interest, for it is the first demonstrated natural occurrence of d(-) glutamic acid and of a polypeptide composed of a single amino acid. There is, in addition, a polysaccharide haptene present in the cell substance of the bacilli, which may be isolated from these bacilli;37 it appears to be the same in both virulent and avirulent strains, and its immunological function is not clear.

The anthrax bacillus also differs from most other aerobic pathogenic bacteria in that it forms spores which are visible as refractile bodies either free or located centrally within the cell. Their diameter does not exceed that of the vegetative cell, and hence the sporecontaining rod is not distorted. Spores are formed most abundantly at 32° to 35° C. and only under aerobic conditions, *i.e.*, not in the circulating blood of infected animals. Germination of the spore is usually polar,

PHYSIOLOGY 615

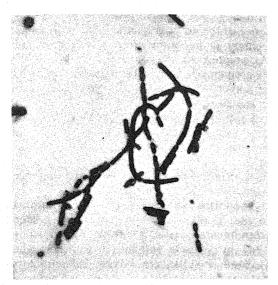

Figure 156. Bacillus anthracis, 48-hour culture on nutrient agar. The spores appear as unstained areas. Note the typical arrangement of the bacilli in coiled chains. Crystal violet stain; \times 1200.

i.e., parallel with the long axis, but rarely may be equatorial.

The bacilli stain readily, but often unevenly, with the usual aniline dyes. The granular material within the cell consists of fat, volutin, or glycogen. The bacillus is gram-positive. The spores are stained with difficulty but, after staining with hot carbol-fuchsin, are equally difficult to decolorize; hence the vegetative cells may be decolorized and stained with a contrasting dye.

The colonies of the anthrax bacillus are irregular and have a curled or hair-like structure, giving what is sometimes called a "Medusa head" appearance. On microscopic examination tangled coils of long chains of bacilli may be found. This colonial appearance is closely simulated by *B. subtilis* and some other related saprophytic, aerobic, spore-forming bacilli.

Physiology. The anthrax bacillus grows readily upon all the ordinary laboratory mediums, and growth is not improved by the addition of enriching substances. It can be grown on simple synthetic mediums; thiamin, magnesium, iron, and calcium are required together with a source of energy, and uracil, adenine, guanine, and manganese markedly stimulate growth. Growth occurs at temperatures as high as 41° to 43° C., with an optimum at 37° C. This bacillus is aerobic and facultatively anaerobic. Dextrose and trehalose are fermented rapidly but without

gas production. Sucrose, maltose, and some other carbohydrates are fermented less rapidly; lactose, galatose, mannitol, dulcitol, rhamnose, and xylose not at all. Gelatin is slowly liquefied but indol is not formed, nitrate is not reduced, and little or no hydrogen sulfide is produced. Milk is feebly acidified and is curdled by a rennet-like ferment, and the casein slowly peptonized. On potato a gray, furry growth is produced; spores are formed in particular abundance on this medium.

The anthrax bacillus may be differentiated from other species of Bacillus without difficulty except in the case of the saprophytic form, B. cereus (see differential key below), and a selective medium for the isolation of spores, which contains propagitine (0.01 per cent) and polymyxin B (20 μ g./ml.), inhibits the growth of most nonsporulating aerobic bacilli except Proteus, but does not inhibit the growth of B. cereus.25 Nevertheless, B. cereus is not an avirulent variety of the anthrax bacillus, and the two are at best only distantly related. While animal pathogenicity is the outstanding differential character of B. anthracis, it may be identified with a considerable degree of confidence by the aggregation of physiological and morphological characteristics. 10, 20, 31

The vegetative cells of the anthrax bacillus display the usual degree of resistance to deleterious influences, but the spores are relatively highly resistant, although not so resistant as the spores of B. subtilis and related forms. The bacilli have been isolated from naturally infected soil stored for as long as 60 years. 49 Anthrax spores are usually destroyed by boiling for 10 minutes and by dry heat at 140° C. for three hours. Their resistance to disinfectants is variable, for 0.1 per cent mercuric chloride may fail to kill them in 70 hours, while those disinfectants which are oxidizing agents are much more effective; 3 per cent hydrogen peroxide kills in one hour, and 4 per cent potassium permanganate in 15 minutes. In the animal carcass vegetative cells are destroyed during anaerobic putrefactive changes in 72 hours, but spores are viable under such circumstances for at least nine months. In the soil anthrax spores may remain viable for many years.

Variation. The rough variant is the virulent and naturally occurring form of *B. anthracis*. It was early noted by Pasteur that prolonged cultivation of these bacilli at

higher than optimum temperatures, 42.5° C., resulted in a loss of virulence and the appearance of asporogenous variants. A number of different types of variants are produced by such cultivation at high temperatures or in the presence of dilute antiseptics. Smooth and mucoid types of colonies have been observed, and some of these variants may be nonspore-forming. Virulence is not related to the ability to form spores, for both asporogenous virulent strains and spore-forming avirulent strains may be produced.

Virulence of the anthrax bacillus is, rather, dependent in part on the formation of the glutamyl polypeptide capsule. The bacilli of virulent R type appear rough in the conventional culture because they are not encapsulated, but they produce capsules in vivo and in vitro when the cultures are incubated under increased carbon dioxide tension in bicarbonate-containing mediums, and the colonies are mucoid in appearance. Avirulent R variants resemble the virulent form in culture in air, but the colonies remain rough and capsules are not produced on culture under increased carbon dioxide tension. 12, 45 Avirulent strains may also be encapsulated, producing mucoid colonies in air culture, but do not form toxin.

Toxins. Under ordinary conditions of culture the anthrax bacillus does not produce an exotoxin, nor is the cell substance of the microorganisms toxic. Vaccines prepared with killed bacilli do not produce an effective

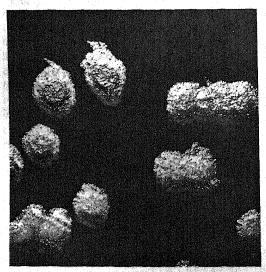

Figure 157. Colonies of *Bacillus anthracis* on nutrient agar, 24-hour culture. Note the large size and coarse texture suggestive of R variants. \times 3.

immunity, and for many years the high virulence of the anthrax bacillus and the toxemia evident in infections were not understood. As pointed out elsewhere (Chap. Nine), the discrepancy between the apparent atoxicity of a microorganism and the toxemia evident in the disease produced by it may be accounted for in two ways; *viz.*, toxicity may be produced by the microorganism only under the conditions of growth in the tissues of the infected animals, or the toxicity may be of host origin and produced by the infected tissues. ^{33, 34}

The former appears to hold true in anthrax in that a toxic substance may be isolated from infected tissue. This was first shown in 1947 by Watson and his co-workers, who isolated a substance having inflammatory activity from the tissues of infected animals. Subsequently, the biological activity present in plasma, edema fluid, and exudates in infected animals was found to be separable into two fractions by high speed centrifugation, one designated fraction I, in the sediment, and the other, fraction II, in the supernatant. Both are mildly toxic, but in combination apparently act synergistically to account for the high toxicity of the unfractionated plasma.35, 38 This toxicity is also produced in vitro in mediums containing large amounts of serum. The serum appears only to facilitate the passage of one fraction of the toxicity through sintered glass filters, and when it is not included the filtrate is atoxic. The activity adsorbed on sintered glass filters was subsequently found to be dual in nature, to give a third component of the anthrax toxin complex.4,36 At present, then, the anthrax toxin appears to contain a protective antigen (PA), an edema factor (EF), and a lethal factor (LF). None of these is toxic when tested alone, but when PA is combined with either EF or LF, the mixtures produce the edema (local) reaction or the lethal reaction respectively. These components are immunologically distinct, but their interrelationships are somewhat uncertain.24

The activity of the toxicity is not yet precisely defined,³² but it appears to be in the nature of an aggressin-like substance, having high antiphagocytic activity, and is consistent with the disease picture of anthrax and the highly invasive character of the microorganism.

Pathogenicity for lower animals.^{9, 39} In nature, anthrax is primarily a disease of

cattle and sheep; horses and swine are susceptible but are less commonly affected. In the period 1945 to 1952, 2785 outbreaks of anthrax occurred in which 14,708 domestic animals were lost in 38 states in this country. Wild deer and other gregarious herbivora are liable to occasional outbreaks.

The smaller rodents are very sensitive to inoculation.21 Rabbits, guinea pigs, and white mice are susceptible in that order. and are fatally affected by the subcutaneous introduction of a very small number of virulent bacilli. The guinea pig is often used as an experimental animal. 30 The white mouse may succumb to inoculation with a single bacillus of a highly virulent strain. Carnivorous animals, though possessing greater resistance than the herbivora, are nevertheless susceptible, as several epidemics in zoological gardens involving leopards, lions, pumas, bears, and other animals have shown. Certain animals possess a marked natural resistance to anthrax. Most rats are quite resistant,43,44 especially the white rat. The mature dog is only slightly susceptible. Birds, especially pigeons, can be infected, but not easily. Frogs are completely resistant, but toads are very susceptible.

The route by which the bacilli enter the body exerts an important influence in both experimental and natural infections. Subcutaneous inoculation is the method most commonly practiced in experimental work and is almost uniformly fatal with the ordinary small laboratory animals. Feeding experiments show that administration of spore-free cultures even to highly susceptible animals is without result, owing to the destruction of the bacilli in the stomach. The feeding of spores, on the other hand, leads to infection of the more susceptible species, although not so certainly as in subcutaneous inoculation; resistant species, such as swine, may be infected through the alimentary tract only with difficulty. Infection through the respiratory tract is possible in the experimental animal² but is probably almost unknown in the lower animals under natural conditions.

In highly susceptible animals the disease is acute and runs a rapid course; the case fatality in cattle and sheep is about 80 per cent. It presents all the characteristics of typical septicemia, and local manifestations may be almost entirely absent. Enormous multiplication of the bacteria takes place in the blood and internal organs, and sections

through the liver or spleen show the capillaries gorged with masses of bacteria. The spleen is a deep red color and greatly enlarged, hence the name splenic fever. The more resistant animal species do not develop this generalized infection, but the bacteria remain localized in an abscess or carbuncle and fail to spread through the body. This is the case with the dog and in some forms of infection in man. Such natural resistance has been found, under experimental conditions, to be separable into two components, resistance to the establishing of an infection, i.e., antibacterial resistance, and resistance to the toxin.¹⁸ Man stands perhaps midway in susceptibility between the dog and the sheep.

Under natural conditions cattle and sheep are infected through the alimentary tract by swallowing spores while grazing in infected pastures. As has been pointed out, spores are able to retain their vitality in soil for a long period, and pastures once infected may infect cattle after a lapse of as many as 30 years. In this country contaminated feed, especially bone meal, has been responsible for the infection of livestock with anthrax. Hides imported from China and other countries where the disease prevails are not uncommonly contaminated with anthrax spores; in the United States several outbreaks of anthrax among cattle with some consequent cases of human infection have been traced to the overflowing of pasture land by streams receiving the drainage of tanneries.

Cattle may also occasionally be infected by direct contact through wounds, abrasions, and other injuries to the skin; but alimentary infection is by far the most common. Anthrax has been experimentally transmitted to susceptible animals by biting flies of various species that had previously fed on animals dying from anthrax. The bacilli persist in the insects for only a short time.

Pathogenicity for man.¹⁴ Three routes of infection of human beings are known: (a) through the skin, (b) through the respiratory tract, and (c) through the alimentary tract. The bacillus is almost always transmitted to man from lower animals rather than from other human beings. The persons most commonly affected are those having to do with cattle and their products, such as butchers, shepherds, herdsmen, and handlers of hides, hair, and fleeces.^{16, 23, 50} In the United States there was a total of 400 cases of anthrax in

the period 1945 to 1955. The incidence of cases of infection from wool and hair increased nearly five-fold in the second five-year period, and over 90 per cent of the infections contracted in tanneries were from goatskins. In the period 1956–1960, 115 cases of anthrax were reported in this country.

During the First World War less efficient preliminary disinfection of hides and bristles permitted the introduction of anthrax-contaminated articles from parts of Asia and South America, and a striking increase in anthrax occurred from the use of shaving brushes-the bacilli were isolated from brushes purchased in the open market in some instances. The bacilli are destroyed on such brushes by soaking in 10 per cent formalin at 110° F, for four hours. Laboratory infections, sometimes fatal, have been known to occur with pure cultures of the anthrax bacillus. The case fatality of untreated anthrax in man is probably about 20 per cent.

Cutaneous anthrax (malignant pustule). The most common form of anthrax in the human subject is due to skin infection and usually takes the form of a localized boil or abscess, which often heals spontaneously but may progress into a septicemic condition

unless checked by incision or other surgical procedure. Owing to the relatively high resistance of man, septicemia does not often occur, especially if the carbuncle is incised and thoroughly drained. Lesions of all sizes may be produced, from a minute pustule to a large abscess.

Pulmonary anthrax. The pulmonary form of anthrax due to inhalation of the microorganisms is the most dangerous, although not the most common, variety of the disease in man. It is an occupational disease among those who handle and sort wools and fleeces and contract the infection by inhalation of spores set floating in the air from the infected material; pulmonary anthrax is known in England as "wool sorters' disease." It is characterized by many of the symptoms of pneumonia and often passes into fatal septicemia. In experimental airborne anthrax a very few spores suffice in the case of virulent strains, entering the tissues from the alveoli via the lymphatic system. The inhaled spores produce only slight local reaction except for clogging of the capillaries in the terminal stage of the disease. It is of some interest that anthrax spores may occur in the nose and throat of healthy persons exposed to inhalation infection without subsequent development of the

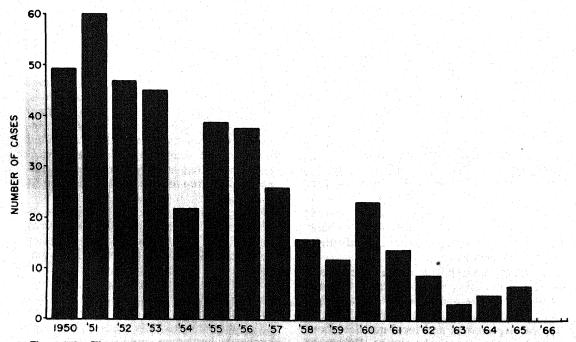

Figure 158. The number of cases of human anthrax reported in the United States during the period 1950-1965. (Morbidity and Mortality Weekly Report, Annual Supplement, Vol. 14, No. 53. Communicable Disease Center, Public Health Service, U. S. Department of Health, Education, and Welfare.)

IMMUNITY 619

disease,¹¹ and serological survey following an outbreak of pulmonary anthrax suggested the occurrence of subclinical infection.^{8, 26} There seems to be no evidence that such persons play any significant part in dissemination of the human infection, and the presence of the microorganisms probably represents no more than a transient contamination.

Intestinal anthrax. The alimentary tract, although the usual path of infection in cattle, is very rarely so in man. A few instances are on record of intestinal anthrax contracted through the medium of spore-infected food. Such cases occur among workers with animal products and have probably been due to lack of caution in handling food with uncleansed hands. Insufficiently cooked meat from anthrax-infected animals may also be a source of intestinal anthrax.

Bacteriological diagnosis. If the specimen is fresh and not grossly contaminated, the anthrax bacillus may be found in gramstained smears as a rule and is readily cultured on the usual nutrient mediums. Such a specimen may also be used for guinea pig inoculation, but it must be borne in mind that the sporulating obligate anaerobes will kill as rapidly as the anthrax bacillus. In any case the isolated culture must be tested for pathogenicity by animal inoculation. The animal will die in 36 to 48 hours after subcutaneous inoculation of a very small amount of culture. A gelatinous infiltration will be found at the site of inoculation, and the tissues of the animal contain enormous numbers of the bacilli; smears of cut spleen, for example, will show many of the large, gram-positive bacilli. This demonstration of pathogenicity is sufficient for identification, since none of the aerobic sporulating rods that resemble the anthrax bacillus are pathogenic for the guinea pig and similar experimental animals.

A precipitation test, the Ascoli test or thermoprecipitation test, is sometimes used to detect anthrax contamination of hides or other tissues. The specimen is extracted with boiling water and the extract used as an antigen in a precipitin ring test with very high titer anthrax antiserum.

Chemotherapy. Prior to the development of the sulfonamides and antibiotics, anthrax was treated with only partial success by a combination of antiserum and arsenicals. While the number of cases is limited by the

low incidence of the disease, it has been found that sulfonamides are effective chemotherapeutic agents, and penicillin remarkably so. In those instances in which the bacilli have been found to be penicillin-resistant, the tetracyclines have been found to be practically equally effective.

Immunity. 42 Natural immunity, or resistance, of certain animal species is very high. This is a consequence, at least in part, of an anthracidal activity present in tissues and associated with a histone-like protein

or polypeptide (Chap. Nine).

Recovery from infection in the susceptible animal results in a solid immunity, and the serum contains protective antibody to high titer. Nevertheless, it has not been possible to produce any appreciable immunity to challenge inoculation by inoculation with killed vaccines of anthrax bacilli, and an effective immunity has resulted only from infection with attenuated strains, as used by Pasteur in his early studies on immunity to anthrax in sheep, or by inoculation with virulent, or partially virulent, strains in conjunction with protective antiserum.

With examination of the immunological activity of the products of *in vivo* growth of anthrax bacilli, as noted above in connection with the toxin, it was found by Cromartie and his colleagues that antigen eliciting an effective immune response was produced *in vivo*, but not ordinarily in culture *in vitro*. In 1946 Gladstone found that the immunizing antigen could be produced in *in vitro* culture in the presence of body fluids containing albumin and a dialyzable fraction replaceable by sodium carbonate. The elaboration of this antigen in culture and its nature have subsequently been studied at length. ^{6, 40}

The immunizing antigen is present in cell-free filtrates of in vivo or in vitro cultures, and apparently diffuses freely from the bacterial cells. It is heat-labile and somewhat unstable but can be preserved by lyophilization, and is protein in nature. It is formed in culture in chemically defined but complex mediums containing many amino acids, purines, glutamine, thiamin, bicarbonate, and other salts.⁵² Certain of the amino acids, bicarbonate and calcium are required for formation of the antigen but not for growth.²⁷ It may be precipitated by alum,⁵¹ or salted out and purified by adsorption and elution.41 The activity is present in maximal amount in young cultures, and there is rea-

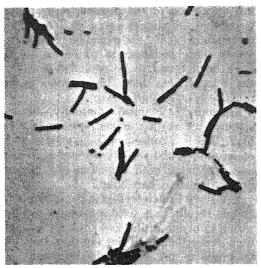

Figure 159. Bacillus subtilis, 24-hour culture on nutrient agar. No spores have formed as yet. Note the typical arrangement of the bacilli. Crystal violet stain; × 1200.

son to believe that it tends to be destroyed by bacterial polypeptidases.

This immunizing antigen is not related to the glutamyl polypeptide capsular substance, although both are required for virulence, and the antigen is produced by avirulent nonencapsulated mutants. It is intimately related to the toxin described above, but the relationship has not yet been precisely defined.

While an effective immunity is produced by prophylactic inoculation with the immunizing antigen, in man as well as monkeys and other experimental animals, the nature of the immunity so produced is not completely clear. ⁴⁷ It presumably includes antibody to the aggressin-like antiphagocytic activity and is antitoxic in that the skin lesion produced by intradermal inoculation in the rabbit is inhibited by immunization; this inhibition has been proposed as a measure of immunity to the infection.⁵

Prophylactic immunization. Active immunization of man to anthrax is not quantitatively significant under ordinary circumstances, but effective immunization of cattle, sheep, and other domestic animals can be of very considerable importance.

Immunization by inoculation with attenuated, partially avirulent bacilli, Pasteur's prophylactic, has been widely used in France for the immunization of domestic animals although infection, "vaccine anthrax," may occur. An alternative method, and one which has been used in this country in areas where

anthrax is prevalent, is Soberheim's method. It consists of the simultaneous inoculation of virulent spore suspension and immune serum from recovered animals. Either method tends to perpetuate anthrax infection.

The possibility that an effective immunity may be elicited by inoculation with sterile, cell-free preparations of the immunizing, or protective, antigen described above is of considerable practical importance. While it is fully established that an effective immunity is so produced, 3, 7, 46 in the absence of some method of quantitating the immunity the efficacy of the antigen is difficult to evaluate. The intradermal reaction noted above and correlation of protection with complement-fixing antibody titer²² have been suggested, but an immunity index has been devised¹³ which appears to be more informative and correlates with antibody titrated by gel diffusion. 19, 28 On the basis of the immunity index it has been found¹⁷ that a nonencapsulated avirulent mutant used as a vaccine gave a 10- to 15-fold increase in immunity, the protective antigen a 1000-fold increase, but immunization with protective antigen followed by inoculation with live vaccine gave as much as 109-fold increase over that of uninoculated animals. Such immunization procedures have not yet been tested on a large scale under natural conditions.

RELATED BACILLI

As indicated earlier, there are many species of aerobic sporulating bacilli closely related to and indistinguishable from the anthrax bacillus on any basis other than pathogenicity. The close morphological similarity led many of the early workers to describe "avirulent anthrax bacilli," "pseudo-anthrax bacilli," and "Bacillus anthracoides." There is, however, little basis for such differentiation. These bacilli are saprophytic soil forms and are commonly found as contaminants on plates because of the wide distribution of their spores in dust.

Of the commonly encountered forms, B. subtilis, B. megaterium, and B. cereus are among the most familiar. B. mycoides, sometimes called B. ramosus, is closely related to B. cereus and is classified as a variety of it rather than a separate species. There are some 30 species of Bacillus in all. The following portion of a key to the genus indicates the manner in which species are sepa-

rated and defined. The close relation of the anthrax bacillus to the saprophytic forms is noteworthy.

Mesophilic, aerobic bacilli with spores ellipsoidal to cylindrical and central to terminal:

- (I) Diameter of vegetative cells less than 0.9 μ (small cell variety)
 - (1) grow at pH 6.0; acetyl-methylcarbinol formed (a) gelatin hydrolyzed
 - (i) starch hydrolyzed; nitrate reduced to nitrite

Bacillus subtilis

- (ii) starch not hydrolyzed; nitrate reduced to nitriteBacillus pumilus
- (b) gelatin not hydrolyzed Bacillus coagulans
- (2) no growth at pH 6.0; acetyl-methyl-carbinol not formed
 - (a) casein digested; urease not formed Bacillus firmus
 - (b) casein not digested; urease formed Bacillus lentus
- (II). Diameter of vegetative cells 0.9 μ or more (large cell variety)
 - (1) acetyl-methylcarbinol not produced Bacillus megaterium
 - (2) acetyl-methylcarbinol produced
 - (a) saprophytic, usually motile

 Bacillus cereus

 Bacillus cereus var. mycoides
 - (b) pathogenic, nonmotile Bacillus anthracis

These forms can be distinguished from one another on the basis of details of spore formation, differential fermentations, and the like, and constitute stable types. Immunological investigation has confirmed the homogeneity of these types also. The im-

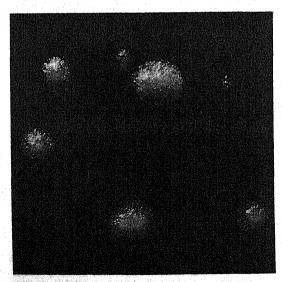

Figure 160. Colonies of *Bacillus subtilis* on nutrient agar, 24-hour culture. Note the resemblance to colonies of the anthrax bacillus. \times 3.

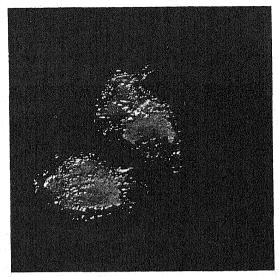

Figure 161. Colonies of *Bacillus mycoides* on nutrient agar, 24-hour culture. × 3.

munological specificity of the spores appears to be different from that of the cell substance, and four main types of the small cell group can be distinguished, though differentiation of the large cell group by this means is not so satisfactory. Similar results have been obtained in studies of the specificity of the cell substance.

The pathogenicity of these forms is very slight at best, but B. subtilis is occasionally responsible for infection,48 particularly of the eye, and rarely may produce septicemia in the immature animal. Other bacteria of this group are occasionally found to have feeble pathogenic powers. Heaslip¹⁵ isolated an aerobic sporulating bacillus, which he called B. tropicus, by the inoculation of mice with blood from persons suffering from a mild infection in Australia called "coastal fever." This bacillus has also been found there as a natural parasite of the rat and the bandicoot. It appears to be very similar to a bacillus described by Scott many years before as B. seroficus. B. alvei, the cause of foul brood of bees, is not pathogenic for man.

Chapter Twenty-nine

CLOSTRIDIUM — THE SPORE-FORMING ANAEROBES

The group of anaerobic sporulating bacilli includes a variety of forms. 53, 77 Some of these, the anaerobic nitrogen-fixing bacteria, the butyl alcohol and acetone-producing forms, and others, have been discussed earlier (Chap. Five). Still others, however, are pathogenic for man and lower animals, and the more important of these forms—Clostridium tetani, Cl. septicum, Cl. welchii, Cl. novyi, Cl. histolyticum, Cl. chauvoei, Cl. botulinum, and the nonpathogenic but common species Cl. sporogenes—will be considered here.

The status of these bacteria as parasites is open to some question. They occur in the soil, in particular abundance in manured soils, and are found in the intestinal tract of man and animals. Cl. welchii, for example, is uniformly present in human feces, and the tetanus bacillus is often found (in up to 40 per cent of specimens examined) in the feces of domestic animals. It has been assumed by some that these bacilli are parasitic and their presence in the soil is a consequence of contamination. Although their numbers are unquestionably greatly increased by manuring and other forms of contamination, some have been found in virgin soils. It is perhaps best to regard them as essentially saprophytic soil forms that are capable of maintaining themselves in the large intestine.

None of these bacteria possesses any marked ability to invade the body tissues by itself. Cl. botulinum is apparently incapable of setting up an infection, while others, such as the tetanus bacillus, produce local infections when aided by traumatic injury to the tissues and frequently by the

presence of other bacteria. Still others, such as the bacilli associated with gaseous gangrene, show pronounced invasive properties when once established, but the initial invasion is made possible by other factors, usually trauma and the presence of other bacteria.

The pathogenicity of the anaerobic bacilli is, rather, attributable to their ability to form powerful exotoxins, a property which is curiously confined to these bacteria, the diphtheria bacillus, and the Shiga dysentery bacillus. In the case of botulism the toxin is preformed outside the animal body and, since it is unique in that it is resistant to the digestive enzymes, enters the body by way of the alimentary tract and absorption into the tissues. In the other cases a focus of infection is established, and the toxin formed at that point is disseminated through the body. In some instances, such as gangrene, an extensive local destruction of tissue occurs, but in general the diseases caused by these bacilli are essentially toxemias.

It will be clear from the foregoing considerations that infections with the sporulating anaerobes are not common under ordinary circumstances, for in most instances traumatic injury is a preliminary to infection. On the battlefield, however, such injuries are common, and tetanus and gangrene are not infrequent complications of war wounds. Such anaerobic wound infections were prominent in World War I, perhaps as a consequence of battles fought over the heavily manured fields of France. The occurrence of gaseous gangrene during World War II among troops in North Africa where the desert soil is relatively free of such forms

suggests that clothing may be a more important source of contamination than had been supposed.

Cl. histolyticum is micro-aerophilic, i.e., it will grow in the presence of small amounts of oxygen, but the remainder of the forms considered here are obligate anaerobes. They may be isolated in pure culture by picking colonies from a shake culture or from plates incubated in an anaerobic jar. All are large gram-positive rods, nonencapsulated with the exception of Cl. welchii, and motile by means of peritrichous flagella with the exception of Cl. welchii. Spores are usually of a greater diameter than the vegetative cells, and the spore-containing cells are spindle- or club-shaped. The spores of the tetanus bacillus are round and termi-

nal, and those of the other bacilli oval and subterminal. Two general physiological types of anaerobic bacilli may be distinguished, the one predominantly fermentative or saccharolytic and the other predominantly proteolytic. These and other characteristics are summarized in the accompanying table.

Large amounts of volatile organic acids are produced in the fermentation of carbohydrates by these bacilli; they differ in this respect from the other pathogenic bacteria which produce nonvolatile acid, i.e., lactic acid, for the most part. Amino acids are vigorously attacked by the obligate anaerobes; some are "fermented" to organic acids, while others are mutually oxidized and reduced.

Clostridium tetani

Tetanus is a disease of man and animals characterized by spasms of the voluntary muscles. The spasms are often most marked in the muscles of the jaw and neck, hence the name "lockjaw." Tetanus bacillus was first described in 1884 by Nicolaier, who observed it in the pus taken from mice and other animals that had died after subcutaneous inoculation with small quantities of soil. Kitasato isolated the microorganism in pure culture in 1889 and established its etiologic relation to the disease. He also showed the inability of the tetanus bacillus

to invade the blood stream and showed the disease to be an intoxication. In 1890 von Behring and Kitasato laid the basis for antitoxic therapy in their discovery of diphtheria and tetanus antitoxins.

Morphology. Individual tetanus bacilli are slender, motile (20 to 30 peritrichous flagella), gram-positive, sporulating rods with rounded ends. Their common dimensions are 0.3 to 0.5μ in width and 2 to 5μ in length, but vegetative filaments of much greater length occur. The shorter forms are usually straight; filaments tend to curve in

[†]Acid.

[‡]Strong, moderate, and weak.

an undulating manner. Short chains or rods may occur. The spore is spherical and terminal and larger in diameter than the vegetative cell; spore-containing cells have a characteristic drumstick appearance. Isolated colonies in deep dextrose agar have a wooly appearance and may either be floculent or have an opaque center. Surface colonies are flat, rhizoid, or even feathery, and frequently exceed 1 mm. in diameter. Later the centers may become slightly raised. Colonies on blood agar show hemolysis.

Physiology. The tetanus bacillus develops in plain or dextrose broth and in brain, meat, agar, and gelatin mediums from which the air has been expelled by heating and excluded by some form of seal. If the depth of mediums is adequate, say 7 to 12 cm., no special seal is required, especially for the more viscous mediums. Growth occurs between 14 and 43° C.; the optimum temperature is 37° C.

The growth of *Cl. tetani* is influenced greatly by the presence of associated microorganisms. In sugar-free mediums it may be grown in mixed cultures upon the surface of culture mediums in contact with air through the absorption of oxygen by the associated aerobes. But in dextrose broth the growth of the tetanus bacillus in mixed culture is likely to be inhibited by acid

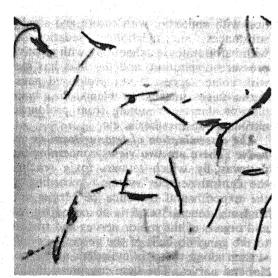

Figure 162. Clostridium tetani in pure culture. Young, actively growing culture showing beginning of spore formation. Note the refractile, unstained spores, the drumstick appearance when these are attached to the cells, and the tendency of the vegetative cells to remain attached end to end. Fuchsin; × 1150.

formation due to the associated bacteria. Sugar-free mediums, such as meat infusion peptone broth or deep meat or brain mediums, are therefore preferable for initial culture from contaminated material. Pure cultures may be isolated from these initial cultures by deep agar or surface culture methods. It has been supposed that an initial heating of the contaminated material simplifies isolation of the tetanus bacillus by destroving the vegetative cells of other microorganisms that may be present; this method may, however, leave the spores of the tetanus bacillus still badly mixed with those of other aerobic and anaerobic bacteria. some of which may be more resistant than the tetanus spores.

In pure culture, dextrose stimulates growth as in the case of the other anaerobes, although dextrose and other carbohydrates are not fermented by *Cl. tetani*. Sporulation is not inhibited by carbohydrates, as with the fermentative anaerobes; on the contrary, sporulation of the tetanus bacillus is accelerated in dextrose broth.

Growth in gelatin stab is slow at 22° C. Incubated at 37° C. for two to three days, gelatin cultures usually fail to stiffen in the refrigerator. Coagulated proteins, such as blood serum and egg white, are very slowly liquefied. Deep brain and meat mediums may be slightly softened, but never digested fully; after several weeks a slight darkening occurs near the surface exposed to air. The tetanus bacillus is, therefore, only weakly proteolytic. Amino acids are utilized readily but not by paired oxidation-reduction; glutamic acid, aspartic acid, and serine, for example, are attacked directly with the formation of CO₂, NH₃, and acetic and butyric acids. Both amino acids and carbon compounds are readily dehydrogenated. In litmus milk there is reduction of the indicator and sometimes a slight precipitation of the casein. Nitrates are not reduced to nitrites, but hydrogen sulfide and indol are produced.

The tetanus bacillus has been grown in synthetic mediums, 42 and its growth requirements are relatively complex, including the amino acids arginine, histidine, tyrosine, valine, leucine, isoleucine, and tryptophan; the bacterial vitamins riboflavin, pantothenic acid, thiamin, folic acid, biotin, pyridoxine, and nicotinic acid; the purines adenine and uracil; and oleic acid. The formation of toxin is inhibited by iron, and best yields are obtained when as much iron as possible

is taken out of the medium, though very small amounts are required.45 A beef infusion medium containing hog stomach autolysate or tryptic digest of casein, together with glucose, carbonate, potassium, magnesium, and phosphate, allows the production of toxin to high titer.

Spore formation begins in about two days at 37° C. and in eight or 10 days at room temperature. The spores are highly resistant and when protected from light and heat remain viable for years. Theobald Smith found a number of strains that resisted steaming at 100° C. for 40 to 60 minutes. Five per cent phenol is said to destroy tetanus spores in 10 to 12 hours; the addition of 0.5 per cent hydrochloric acid may reduce the time to two hours.

Antigenic structure. The tetanus bacillus is antigenically heterogeneous, and a number of types, designated by Roman numerals, have been described. At present 10 in all are known. Both somatic and flagellar antigens appear to be involved, the former of a group and the latter of a specific nature. Type VI organisms are not flagellated and lack type-specific antigen, and types II, IV, V, and IX have a common O antigen which results in higher titer cross-reactions among these than among the other types.³² Types I and III have been found most commonly in the United States, England, and France. type V in China. The toxin formed by these types is immunologically identical.

Tetanus toxin.93 As indicated elsewhere (Chap. Nine), the potent soluble toxin produced by the tetanus bacillus is of dual nature; tetanospasmin is the portion that affects the nervous tissue and tetanolysin is a hemolysin. The former is by far the more important; there is no indication that tetanolysin has any significance in connection with the ordinary symptom complex. Liquid cultures are usually toxic; 5×10^{-6} ml. may be fatal to a mouse. Although apparently diffusing freely into the surrounding medium82 the toxin is also present in the bacterial cells⁵⁵ and may be extracted from washed cells with molar sodium chloride.

The toxin is filtrable and may be freed from bacteria by filtration through Berkefeld, Chamberland, and similar filters. In aqueous solution the toxin is highly unstable to heat and light and must be stored in a cold dark place. It is apparently protein in nature, or at least has not as yet been separated from protein, and is destroyed by proteolytic enzymes and hence is ineffective when given by mouth. It may be precipitated with ammonium sulfate and in the dry state retains its potency for a long time. It is an excellent antigen and gives rise to high titer antitoxic serums.

As indicated above, tetanus toxin is one of the most potent poisons known, and its toxicity far exceeds that of alkaloids and other substances generally regarded as highly poisonous. It has been prepared in crystalline form by precipitation with methanol in the cold. These preparations contained 5 to 7.5×10^7 LD₅₀ doses for mice per mg. of nitrogen, and tetanus was produced in mice with as little as $0.000013 \text{ }\gamma$ of the crystalline toxin. Usually an incubation period intervenes between inoculation and appearance of symptoms which cannot be reduced to less than eight hours with the usual toxic filtrate, and beyond that point the incubation period is inversely related to the amount of toxin injected. With crystalline material, doses of as much as 500,000 MLD are possible in the mouse, and these large amounts produce symptoms in 30 minutes and death in one hour.

Tetanus toxin appears to act like strychnine, suppressing all types of synaptic inhibition,9 and the ultimate cause of death is asphyxia from spasm of respiratory muscles. This spasm can be released by the use of muscle relaxants and anesthetic agents. Such symptomatic treatment, in combination with antitoxin, with curare and similar substances, succinylcholine, sedation as with barbiturates, tracheotomy with positive pressure respiration, and the like, has met with some success,88 but prolonged anesthesia raises unusual problems, viz., bone marrow damage resulting from prolonged

nitrous oxide anesthesia, etc.

The dissemination of tetanus toxin in the body. There are two views concerning the pathway by which tetanus toxin reaches the central nervous system. According to the experimental evidence of Meyer and Ransom, tetanus toxin is absorbed by the end organs of the motor nerves and travels to the ganglion cells of the central nervous system along the axis cylinders of the peripheral nerves. The time consumed in this passage represents the larger part of the incubation period. The toxin may circulate for a time in the blood, but the only path to the central nervous system lies along the axis cylinders of the motor nerve tract. A

cut nerve takes up the toxin very slowly and a degenerate nerve not at all. Section of the spinal cord prevents the toxin from reaching the brain. Meyer and Ransom believed that the spinal ganglion of the sensory nerve presents a barrier to the advance of the toxin, and that for this reason sensory nerves are unable to conduct the toxin. The remarkable excitation of the motor cells of the spinal cord that is observed in tetanus is not accompanied by characteristic lesions.

Although long generally accepted, this view was challenged by Abel and his coworkers. who proposed the following theory as in accord with their experimental findings: The toxin exhibits both a central and a peripheral action, each of which may be demonstrated independently of the other. The central effect, which is characterized by reflex motor convulsions, is due to the poisoning of the motor nerve cells of the spinal cord, medulla, and pons; the peripheral effect, recognized as the unremitting rigidity of voluntary muscles, results from the fixation of the toxin upon the motor end organs. Following subcutaneous or intramuscular injection the toxin is absorbed by the lymphatics and distributed to the central nervous system by way of the arterial circulation. Normal tonicity of the motor end organs seems to be essential to the development of tetanic rigidity; neurotomy results in an immediate, sharp depression of the tonicity of the myoneural junctions, hence they are not responsive to the influence of tetanus toxin.

Abel's views have not been generally accepted in spite of their support by convincing experimental evidence which cannot be reviewed here. Other experimental data have been presented in support of the theory of the axis cylinder pathway,^{4, 91} and it may be regarded as established.

Tetanus toxin possesses a strong affinity for the cells of the central nervous system. On inoculation into the central nervous system it is rapidly fixed; the fixation time is much less than the latent period, suggesting subsequent action on the nerve tissue, particularly of the medulla. A mixture of toxin and brain substance can be injected into an animal without producing any toxic effect, the toxin apparently entering into a firm combination with some ingredient of the nerve substance. Not only the central nerve cells, but to some extent other tissue cells, are able to bind tetanus toxin. Sub-

cutaneous inoculation is less likely to be fatal than direct inoculation into nerve tissues, because some of the toxin is bound and prevented from reaching the highly sensitive nerve cells.

Pathogenicity. Tetanus is essentially an intoxication. The bacilli set up a localized infection, and the toxin formed there is disseminated through the body and gives rise to the symptom complex characteristic of the disease. Bacillemia may occur very rarely, however, and has been produced experimentally. The bacilli generally gain entrance to the tissues by means of a deep dirty wound which may be relatively small, so small sometimes as to escape serious attention. The widespread occurrence of the tetanus bacillus would seem inconsistent with the relative infrequency of tetanus infection, but mere introduction of the bacillus into the body is not sufficient to produce the disease: the microorganisms must find favorable conditions for proliferation at the site of penetration. Experimentally, pure cultures of vegetative cells or spores that have been freed from toxin cannot germinate in uninjured tissues, but simultaneous inoculation with common saprophytes or with irritant chemicals, such as calcium salts or lactic acid, enables the bacilli to grow and form toxin. As indicated elsewhere, a sufficiently low oxidation-reduction potential is necessary for the germination of tetanus spores, and it is not unlikely that the potential of normal tissues is too high to allow germination but is reduced by injury.

Tetanus in man.3, 67 Tetanus continues to be a highly fatal disease, with a case fatality rate of about 60 per cent in this country; it is claimed that symptomatic treatment as described above may reduce the case fatality rate to as little as 20 to 30 per cent. The incidence of the disease has not changed appreciably since 1947, i.e., after prophylactic immunization with toxoid had been well established by military experience, and averages about 0.3 cases and 0.2 deaths per 100,000 population. In the period 1950 to 1960 the death rate was 0.16, and an average of 465 cases were reported per year.35 Prior to 1948 the seasonal incidence reached a peak in late spring and summer, but since then has shown a peak in late summer and early fall. Half or more of the cases are reported from southern and southeastern states, with Florida having the highest rate of 1.5 and Alabama the next with

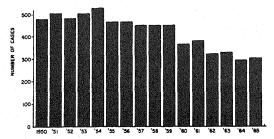

Figure 163. The incidence of tetanus in the United States as indicated by the number of cases reported during the period 1950–1965. (Morbidity and Mortality Weekly Report, Annual Supplement, Vol. 14, No. 53. Communicable Disease Center, Public Health Service, U. S. Department of Health, Education, and Welfare.)

1.3 cases per 100,000 during the period 1951 to 1954. Tetanus neonatorum (see below) is an important factor in these higher rates; in Florida during this period the non-white neonatal mortality rate was 34.3 deaths per 100,000 live births.

While as late as 1925 postoperative or surgical tetanus accounted for as much as 10 per cent of the cases, this has become relatively rare although outbreaks still occur in modern hospitals. It is most commonly associated with faulty sterilization of dressings, and occasionally results from the use of contaminated catgut. The disease may also be associated with uncommon circumstances; for example, tetanus among drug addicts, due to the use of unsterilized needles, syringes, or contaminated drugs, has been observed with some frequency in Chicago, and in a scattered way in other large cities in the United States.

By far the most common kind of tetanus is that following injury, even apparently minor or trivial injury, frequently puncture wounds which facilitate the growth of the anaerobic bacilli. Of a group of 91 cases treated in the Mayo Clinic, 85 29 were from wounds with nails and wood slivers, six other types of puncture wounds, 34 lacerations and abrasions, 17 with miscellaneous foci of infection, and in five cases there was no physical evidence of a wound. This kind of tetanus tends to occur in rural males, especially children.

Tetanus of the newborn or tetanus neonatorum is a consequence of infection of the umbilicus through septic midwifery. It is especially common among the Negroes of the southern states and in other races living under unhygienic conditions, The tonic spasms characteristic of tetanus usually begin at the site of infection, and the initial symptoms may include headache and stiffness of the neck. The spasms may remain localized in mild infections, but usually they are general and involve the whole somatic muscular system. Postmortem findings are insignificant; other than a moderate congestion, the organs show no pathological changes and the initial lesion may, of course, be inapparent or small.

The incubation period of tetanus is variable and may range from two to 50 days. The case fatality is inversely related to the incubation time; it may be as high as 70 to 80 per cent or as low as 15 to 20 per cent. Death, if it occurs, follows relatively soon after the appearance of symptoms; the dictum of Hippocrates, "such persons as are seized with tetanus die within four days, or if they pass these they recover," still stands. When the disease has a prolonged incubation period, a less sudden development of symptoms, and consequently more favorable prognosis, it is sometimes termed "chronic."

Tetanus in lower animals. Tetanus is not a rare affection in the horse, the symptoms and course of the disease being similar to the disease in man. Cattle, sheep, and hogs are less commonly affected. Experimentally, tetanus can be produced in mice and guinea pigs by the inoculation of spores introduced on splinters of wood and also by injection of toxin. The feeding of animals with tetanus bacilli, spores, or toxin is without effect. Tetanus differs from most other infectious diseases in that the diseased animal is not an appreciable factor in the spread of infection. A normal horse may distribute tetanus spores quite as widely and freely as a horse sick with tetanus.

Immunity. As indicated earlier, tetanus toxin is an excellent antigen, and high titer antitoxic serums may be prepared. Horses are good producers of antitoxin and are immunized by toxin-antitoxin mixtures followed by toxin alone. In France toxoid is used for the first injections. Because of hypersensitivities to horse serum protein, there has been some interest in human antitoxin, but the amounts available are necessarily limited.⁷³

The standardization of antitoxin. The American immunity unit is defined as "ten times the least quantity of antitetanic serum necessary to save the life of a 350 gm. guinea pig for 96 hours against the official

test dose of a standard toxin furnished by the Hygienic Laboratory of the Public Health and Marine Hospital Service." The official test dose is about 100 guinea-pig MLD's of a precipitated standard toxin. It may be noted that the L_o rather than the L+ end point is determined. Thus the tetanus antitoxic unit has slightly more than 10 times the experimental protective power of the diphtheria antitoxic unit. An antitoxic unit strength of 900 per ml. may be attained exceptionally. Practice has been different in other countries, however, and the Permanent Committee on Standardization of the Health Organization of the League of Nations found that 1 German unit, 66 American units, and 3750 French units were equivalent. It has been agreed that the international unit shall be one-half of the American unit.69

The appearance of multiple zones of precipitation has interfered with the application of the Ramon flocculation method to tetanus toxin, toxoid, and antitoxin. It has been reported that a specific flocculation zone occurs with refined enzyme-treated antitoxin. Antitoxin may also be titrated by passive hemagglutination—e.g., erythrocytes are sensitized with purified toxoid—and the correlation of such titers with those obtained by bioassay in the mouse have been reported to be very good. 84

The antitoxin deteriorates with time, the most important factor being the temperature at which it is stored. During storage for one year in the refrigerator no potency is lost, at room temperature the loss is 7 to 9 per cent, and at 37° C. it is 44 to 47 per cent.

The prophylactic use of antitoxin. 18, 79 In veterinary practice, tetanus antitoxin has been used prophylactically with a high degree of success. Vaillard collected the statistics from 1896 to 1906 of eight veterinary surgeons who inoculated 13,124 animals after operations or accidental wounds without the occurrence of a single case of tetanus. During the same time two veterinary surgeons alone saw 139 cases of tetanus among animals which did not receive the treatment. The figures of Nocard and Labat added to Vaillard's data cover the cases of 16,917 animals receiving prophylactic injections; among them only one horse had tetanus. In this case the antitoxin was given five days after the wound and the attack was mild.

It is probable that in many cases tetanus

is averted in man by the prophylactic use of antitoxin. Even though the disease is not prevented, the incubation period is delayed, and the disease may be very mild or remain localized. Precise statistical evidence involving comparable series of controls is not available, but the experience of World War I was that with increased use of tetanus antitoxin there was not only a lower incidence of the disease but an increase in mild and chronic cases. Passive immunization provides antibody in the circulating blood which combines with toxin and renders it harmless. The avidity of the nervous tissue for tetanus toxin is very great, however, and symptoms may appear in spite of the presence of circulating antibody.

Passive immunization is necessarily transient since the foreign immunoglobulin is metabolized by the recipient. The half-life of horse serum globulin in man has been calculated to be seven to 14 days, while that of human globulin, as in antitoxin of human origin, is about four weeks.⁷⁸

From time to time attempts are made to passively immunize the newborn by maternal immunization during pregnancy via transplacental antibody. In general this has not proved satisfactory, but the procedure has given encouraging results where neonatal tetanus is common.⁷⁴

The therapeutic use of antitoxin.68 Tetanus antitoxin appears to have but limited therapeutic value. It is obvious, of course, that symptoms result from damage to nerve tissue, and the administration of antitoxin will neither repair such damage nor displace the more avid nerve tissue already in combination with toxin. Reports on the therapeutic value of antitoxin are conflicting; some workers contend that intrathecal administration either alone or combined with intramuscular injection has a beneficial effect. The records of Cook County Hospital in Chicago, however, show that the therapeutic use of antitoxin has not reduced the mortality from tetanus there. It has been reported that mortality may be reduced somewhat, from 76 to 49 per cent, by the use of very large amounts of antitoxin.¹¹ Antitoxin is ordinarily given intramuscularly in man, but under experimental conditions antitoxin by the intracerebral route has therapeutic value,75 raising the question of intrathecal administration in man.

Active immunization.^{25, 71} Considerable emphasis has been placed upon active im-

munization against tetanus, particularly by the French workers. In a summary of the results of 12 years' experience with active immunization of horses and men with formol toxoid, Ramon⁷⁰ states that in one cavalry unit in which tetanus was endemic more than 50,000 horses were immunized over a 10-year period and tetanus has practically disappeared, and in a million and a half human beings immunized with toxoid no case of tetanus has occurred.

With the beginning of World War II, active immunization against tetanus was adopted by the armed services of France. Britain, and the United States. Both fluid and alum-precipitated toxoid are used, in this country the former by the Army and the latter by the Navy, and appear to be equally effective though three doses of fluid toxoid are required as against two doses of alum-precipitated toxoid. No international standard exists for tetanus toxoid; the United States Army specified that the toxin contain at least 10,000 guinea-pig MLD's per ml. and be detoxified with 0.4 per cent formalin; the final preparation must be atoxic for guinea pigs in 5 ml. amounts, and pigs receiving 1 ml. as an immunizing dose must be able to withstand 10 MLD of toxin at the end of six weeks. The importance of more than one immunizing inoculation is illustrated by the observation that the mean antitoxin titer after two inoculations was 0.35 IU (International Units), but with a third inoculation 10 months later the mean titer rose to 10 IU and 18 months later was still 0.37 IU.

More precise examination of the immunogenic potency of toxoids has shown that those prepared in different laboratories may vary widely in this respect, giving an immune response in protective units ranging from 0 to 1149 IU per ml. of serum.³⁰ An international standard has been defined²⁹ which should reduce this variability. The guinea pig is used in assaying immunogenic potency, but the use of the mouse has been urged by many.¹²

The response to booster inoculation is extremely rapid in persons giving an anamnestic reaction, so much so that booster inoculation with toxoid may be substituted

A CONTRACTOR STORES

 for prophylactic antitoxin under circumstances indicating prophylaxis. Prophylactic toxoid was given as a standard procedure to American military personnel during World War II, while British personnel received antitoxin; there was no significant difference in the incidence of tetanus between the two services.

Detectable antitoxin and ability to respond to booster inoculation may persist for as long as 15 years⁵² but it is usually recommended that booster inoculation be given at four year intervals.^{40, 47}

In practice this immunization appears to be highly effective. In the period 1942 to 1945 only 12 cases of tetanus occurred in the United States Army, of which six were in unimmunized persons; four cases occurred in the United States Navy, of which three were in unimmunized persons; in contrast a tetanus rate of about 10 per 100,000 wounded prevailed in the Japanese army and navy, which did not practice routine immunization. British experience in the Middle East war zone similarly indicated an effective immune response, though in most cases only two doses were given. The success of active immunization, coupled with the low incidence of untoward reactions (reported to be 1 in 10,000 immunizations with improved toxoid), has suggested its more general application in civil life. In France, where active immunization to tetanus has been of more and earlier interest than elsewhere, it has been made compulsory as with diphtheria immunization. Tetanus toxoid is now customarily given to children in combination with diphtheria toxoid and pertussis vaccine in this country.

Chemotherapy. The chemotherapeutic drugs are not an important adjunct in the treatment of tetanus. As pointed out above, the disease is primarily a toxemia, and the symptoms are a consequence of tissue damage by the toxin. Antitoxin is mandatory to neutralize as yet uncombined toxin, but the chemotherapeutic drugs have no antitoxic activity. There is some evidence that penicillin and tetracyclines partially protect against experimental tetanus when used prophylactically, but active or passive immunization is much more effective.

With the case of the case of the case of

The state of the s

Gaseous Gangrene 50, 60, 76

Gaseous gangrene is a syndrome which often follows dirty lacerated wounds, especially those involving fractures. It is a characteristic complication of war wounds. and present knowledge of this affection was largely developed during the First World War. But this disease is by no means so rare in civil life as was formerly thought. The increased number of injuries in automobile accidents is responsible for many cases of gangrene. Men injured about railroad tracks, either employees or vagrants, seem particularly prone to develop gaseous gangrene if not properly and promptly treated. Certain forms of peritonitis, appendicitis, intestinal obstruction, puerperal sepsis, and postoperative infections (particularly after laparotomy) are etiologically closely related to it.

The trauma usually, and perhaps necessarily, preceding the development of gangrene results in a local area of tissue anoxia, anaerobic oxidation of carbohydrate continues, and the local reducing intensity drops to levels permitting growth of the obligate anaerobes. Under the conditions of increasing acidity, the catheptic enzymes of the muscle tissue are activated, and free amino acids accumulate as a consequence of the proteolysis to provide an adequate nutrient medium for the invading microorganisms.

Gangrene is usually a mixed infection, and both aerobic and anaerobic bacteria may be isolated from a single gangrenous lesion. The aerobic and facultative anaerobic forms, such as streptococci and coliform bacilli, are not primarily concerned in the development of the pathological process but may contribute indirectly to it by facilitating the exhaustion of locally available oxygen. The gangrenous process is, rather, a consequence of the activity of the sporulating obligate anaerobes and the exotoxins produced by them. It is of more than passing interest that many of these toxins are enzymes; in addition to hyaluronidase, lecithinases, collagenases, and others are produced that have hemolytic, necrotizing, and lethal effects upon the host and host tissues.48 In the fulminating form of gaseous gangrene the muscle tissue becomes filled with gas and with a serosanguineous exudate depending for its character upon the properties of the associated microorganisms.

Of the various species of pathogenic

clostridia, Cl. welchii is usually the most frequently found, closely followed by Cl. novyi and Cl. septicum. The nonpathogen Cl. sporogenes is also found in a considerable proportion of cases; its contribution to the pathology of gangrene is uncertain and it seems probable that its common presence is a reflection of its ubiquitous distribution. Various compilations of the incidence of the several species of Clostridium found in gangrene have been made, and these do not differ significantly from one another. The frequency of occurrence of some of the more commonly found species is illustrated in the accompanying table compiled from World War II data of various authors. It is evident from this that the bacteriology of gaseous gangrene is complicated, and while there is, in effect, a typical form of gaseous gangrene, (a) it is not always produced by the same microorganism; (b) it is frequently caused by several associated agents; (c) it is often the complex result of the combined action of these principal anaerobic bacilli with various other bacteria which play an indeterminate accessory role.

THE VIBRION SEPTIQUE, CLOSTRIDIUM SEPTICUM

In 1877 and 1881 Pasteur, while studying anthrax, produced septicemia in rabbits and guinea pigs by the inoculation of putrid blood from a cow. The affection could be communicated from individual to individual, and a sporulating, motile, rod-shaped anaerobe, considered by him "one of the vibrions of putrefaction" (the actively motile bacilli sometimes appear to be curved), was regarded as the cause of the septicemia and named "vibrion septique."

In 1881 Koch described the pathological effects of a microorganism which he declared identical with the vibrion septique of Pasteur. But this bacterium failed to produce septicemia in guinea pigs, and since its pathogenic effects were limited largely to the site of inoculation, Koch designated it "the bacillus of malignant edema."

Neither Pasteur's nor Koch's description would now suffice to identify with certainty the microorganisms in question. Fortunately, the original strain of Pasteur's vibrion septique has been maintained in France, so that its outstanding characteristics are well known. The lack of any such legacy from Koch in Germany, due to his failure to recover cultures, has led to an all but interminable discussion as to the properties of the true bacillus of malignant edema. The vibrion septique is now generally known as *Cl. septicum*.

Morphology. The vibrion septique is a gram-positive, sporulating, spindle-shaped rod, or filament, and in young cultures it is motile, with many peritrichous flagella. The ends are slightly rounded and the spores, which are oval, are usually median and swell the vegetative cell into a clostridium previous to their release. Spores are formed only in mediums not containing fermentable carbohydrate in excess. The long chains and filaments of these microorganisms which occur on the visceral surfaces of infected guinea pigs are of high differential value. Capsules have never been observed. Deep colonies in 1 per cent agar are transparent or semitransparent. Hemolysis occurs on blood agar.

Physiology. Cl. septicum is a strict anaerobe and develops readily in deep brain or tissue mediums, producing gas rather abundantly. These mediums are not discolored even in the presence of metallic iron. Gelatin is liquefied, but coagulated serum and other proteins are not digested or blackened. Hydrogen sulfide is produced but indol is

not. Dextrose, levulose, galactose, maltose, lactose, and salicin are fermented; mediums not containing one of these sugars support only slight growth. Sucrose, inulin, mannitol, and dulcitol are not fermented. The fermentation of salicin and nonfermentation of sucrose allow the biochemical differentiation of *Cl. septicum* and *Cl. chauvoei*, for the latter does not ferment salicin but does ferment sucrose.

Antigenic structure and toxin. Strains of Cl. septicum are immunologically related but distinct. Six groups have been distinguished on the basis of two O and five H antigens.57 These bacilli are immunologically related to Cl. chauvoei. The toxin formed, however, is specific, but a relatively weak lethal agent. The MLD for mice is about 0.005 ml. Bernheimer⁵ has prepared a dialyzable medium containing casein hydrolysate, cystine, tryptophan, glutamine, biotin, thiamin, nicotinic acid, pyridoxine, glucose, thioglycollic acid, and inorganic salts which supports the growth of some strains with the formation of 400 to 500 mouse LD₅₀ doses of toxin per ml. When injected into animals it produces a gelatinous edema and some local necrosis of the tissues. The toxin has a specific cardiac action in the cat and rabbit, producing a fall in systemic and a rise in venous blood pressure, and in the cat a specific constriction in the pulmonary and coronary circulations, with edema of the lungs and loss of fluid from the circulation. This lethal necrotic toxin, or α -toxin, is an oxygen-labile hemolysin. The toxin is neutralized by *Cl. histolyticum* antitoxin,³¹ but the affinities of the toxins are greater for homologous than for heterologous antitoxins.⁸⁰ The β -toxin is a deoxyribonuclease which attacks the nuclei of rabbit leucocytes. Hyaluronidase is formed also, and is sometimes referred to as the γ -toxin.⁵⁶

Pathogenicity. Cl. septicum does not occur in gaseous gangrene of man as frequently as some of the other anaerobic bacilli but has been found both alone and in mixed cultures. It has been recovered from gaseous infections in cattle and may be one of several microorganisms responsible for blackleg, usually considered a specific disease due to Cl. chauvoei. It has also been found in gaseous infections of hogs and other domestic animals. Experimentally the vibrion septique is strikingly pathogenic for chickens, pigeons, rabbits, guinea pigs, rats, and mice. In such animals the bacteria develop rapidly, producing gas and a reddish, serous edema. They invade the adjacent tissues and the circulation, producing septicemia, which is usually fatal within 24 to 48 hours; sublethal doses do not produce any reaction. Impression smears from the tissues, and especially from the liver, usually show elongated filaments or chains as contrasted with the single bacilli found in animals killed with Cl. chauvoei.

Antitoxic serums which are prophylactic and, to some degree, curative may be prepared by injection of *Cl. septicum* toxin into horses. The antiserums do not have the high antitoxin content that is found in antitetanic serums. Polyvalent commercial serums for prophylactic and therapeutic use in wound infections often contain septicum antitoxin.

CLOSTRIDIUM WELCHII (CLOSTRIDIUM PERFRINGENS)

Cl. welchii was first cultivated by Achalme in 1891 and supposed by him to be the cause of articular rheumatism. In 1892 Welch and Nuttall isolated this bacillus from the foamy organs of a cadaver and called it Bacillus aerogenes capsulatus. Found by Frankel the following year, it was designated B. phlegmonis emphysematosae, and in 1897 Veillon and Zuber called it B. perfringens.

Sometimes called Frankel's bacillus in Germany, Cl. perfringens in France, and Cl. welchii in English-speaking countries, it is designated Cl. perfringens by Bergey.

Morphology. Cl. welchii is a plump, nonmotile, gram-positive rod of variable length, occurring in chains and singly. Capsules are usually present in preparations made from the organs or body fluids. Spores are formed sparingly and only in the absence of fermentable carbohydrates: they are centrally located, are rarely subterminal, and do not swell the vegetative cell in which they are formed. Isolated colonies in deep agar are compact, opaque, white or grayish white biconvex discs. On blood agar the round, smooth, opaque, entire-edged colonies are relatively large, 2 to 5 mm. in diameter, and surrounded by a zone of hemolysis. An exceedingsly useful selective and differential medium containing polymyxin B and neomycin, and iron citrate to give black colonies, has been devised which allows rapid enumeration of the microorganisms.51

Physiology. Cl. welchii is a strict anaerobe and grows readily in deep brain, meat infusion broth, agar, and gelatin mediums. Growth in sugar-free mediums is restricted. Optimum conditions are provided by mediums containing fermentable carbohydrates, but such cultures are often short-lived because of the lack of spore formation and the destructive action of the formed acids on

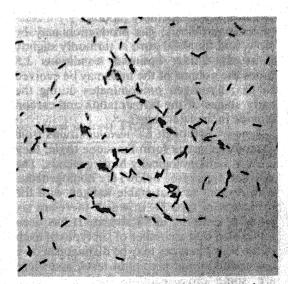

Figure 165. Clostridium welchii from pure culture. Note the relatively smaller size of these bacteria and the central spores. Fuchsin; × 1050.

the vegetative cells. Brain and meat mediums are not blackened normally, but the presence of metallic iron produces a distinct discoloration. Gelatin is liquefied, but coagulated serum or egg is not digested. Hydrogen sulfide is produced, indol is usually said to be negative, but its formation is uncertain.

Nutritive requirements are complex, and semisynthetic mediums which support growth include casein hydrolysate or 19 amino acids together with pantothenic acid, thiamin, nicotinic acid, riboflavin, biotin, folic acid, pyridoxine, adenine, guanine, uracil, inorganic salts including those of manganese and iron, together with glucose. The production of α -toxin (see below) requires two additional substances, one found in enzymatic digests of certain proteins, and the other an alcohol-soluble constituent of pancreas; glyceryl phosphocholine appears to be in part responsible for the activity of the latter.

Acid and gas are produced in glucose, maltose, lactose, and sucrose; neither mannitol nor salicin is fermented; some strains ferment inulin and some glycerol. Broth containing fermentable sugars become markedly turbid with abundant gas formation, and many cultures, possibly all at certain stages, become stringy and viscid. Milk is fermented with a characteristic "stormy" evolution of gas, followed by coagulation of the casein due to acid formation, and the curd is shortly torn to shreds by the continued evolution of gas within. The curd is not digested. This "typical" reaction is considerably modified by incomplete anaerobiosis; gas production may be slow, and the solid curd is torn only slightly if at all. Under optimum conditions 3.8 times the volume of the milk may be evolved as gas; hydrogen predominates during the early stages of the fermentation and carbon dioxide in the later stages.

Types. Although *Cl. welchii* strains from gaseous gangrene form the same toxin, they are not immunologically homogeneous. The Wilsdon types (see below) are homogeneous with respect to heat-stable antigen with the exception of type D, in which there are six kinds of antigens in 13 strains. It has been found also that a number of subtypes of each of the Wilsdon types may be distinguished by agglutination and precipitin tests, and there are some cross-reactions between types. The common antigen appears to be a capsular polysaccharide. As yet, however, sero-

logical identification of *Cl. welchii* is not practical, and gel-diffusion studies of the soluble antigens of the several types has indicated that the group tends to be heterogeneous, and there is considerable strain variation within type.²⁰ Four biochemical types have been suggested on the basis of differences in the fermentation of glycerol and inulin, but these fermentative differences do not appear to be correlated with other variable characteristics.

Toxigenic bacilli closely resembling Cl. welchii and having immunologically related toxins have been isolated from lower animals. These are the lamb dysentery bacillus (B. agni), a bacillus causing a disease of sheep called "struck" (B. paludis), and a bacillus responsible for an enterotoxemia of sheep (B. ovitoxicus). Wilsdon proposed that these be designated Cl. welchii but that four types be distinguished: Cl. welchii type A-the gaseous gangrene bacillus; Cl. welchii type B—the lamb dysentery bacillus; Cl. welchii type C-the "struck" bacillus; and Cl. welchii type D-the bacillus of enterotoxemia of sheep. Two other differentiable types were described subsequently. That designated type E has been found to be a cause of enterotoxemia of lambs and calves, and type F produces enterotoxemia of man, enteritis necroticans.19,58 Re-examination has indicated, however, that type F may not be a valid type and should be merged with type C.81 Unless otherwise indicated, however, the name Cl. welchii refers to the gaseous gangrene bacillus, or type A.

Toxins. It has been shown that, as a group, these bacilli form a number of immunologically distinct toxins and that the observed interrelationships of the toxins formed by the various types are attributable to the sharing of one or more of these components. ⁶² The effects produced by these toxins are as follows:

The α -toxin is hemolytic, lethal to mice on intravenous injection, and produces necrosis on intradermal injection into guinea pigs and rabbits. Termed by Wilsdon the W factor and designated by some workers as the ζ -toxin.

The β -toxin is not hemolytic, mice injected intravenously develop spasmodic twitchings and die almost immediately, and it produces skin necrosis in guinea pigs and rabbits. Termed by Wilsdon the Z factor.

The γ -toxin is not hemolytic, does not produce skin necrosis in guinea pigs, and is lethal to mice.

The 8-toxin is hemolytic but is not lethal to mice and does not produce skin necrosis.

The e-toxin is not hemolytic, but produces skin ne-

crosis in guinea pigs and rabbits and is lethal to mice. Termed by Wilsdon the X factor.

The θ -toxin is hemolytic and lethal and probably produces necrosis in high concentrations. It is oxygen-labile and thermolabile and very similar in properties and immunological specificity, though not identical, to streptolysin O. It is the same as Prigge's toxin.

The η -toxin has lethal activity only. It has been found in only one strain (Lechien) of type A as yet examined, and its occurrence or absence in the other types is not definitely established.

The κ -toxin is a collagenase and is necrotic on intradermal inoculation and lethal on intravenous inoculation in the rabbit. A related but differentiable activity, the λ -toxin, is not active on collagen but on altered collagen such as hide powder.

The *i*-toxin is a lethal toxin, apparently formed as a prototoxin and activated by protease activity; it is only transiently present in the growing culture.

The λ -substance is not a toxin but a proteolytic enzyme whose presence or absence is associated with type.

The μ -toxin is the name given to hyaluronidase formed by these bacilli.

The ν -substance is a deoxyribonuclease which is formed by all types of Cl, welchii.

The optimal conditions of pH, incubation time, and composition of the medium differ from one toxin to another, and a type producing more than one toxin will produce only those for which the conditions are optimal. The distribution among the Wilsdon types of the ability to form these toxins is indicated in the accompanying table. The terminology of the toxins has been somewhat confused owing to differences in the terms used by various workers; that used here has been generally agreed upon.

Of these the α -toxin has been of greatest interest, since it is associated with the virulence of the bacilli. It is a hot-cold lysin, and hemolysis is demonstrable by incubation at 37° C. for 30 minutes, followed by chilling at 2° to 4° C. The hemolysis is dependent

upon the presence of calcium or magnesium (viz., 0.0025 M calcium acetate) and is, therefore, inhibited by phosphate. The α toxin is also a lecithinase. It was observed independently by Nagler and by Seiffert in 1939 that the addition of toxic filtrate to human serum produces an opalescence, and this is known as the Nagler reaction. The opalescence is due to the splitting of lipoprotein with the liberation of free fat and has been developed as a quantitative assay of the activity by turbidity produced in saline extract of egg yolk, "lecithovitellin.36 The free lecithin is hydrolized to phosphocholine and stearyloleylglyceride; since the phosphocholine is water-soluble, the activity may be estimated by measurement of the liberated water-soluble phosphorus under standard conditions.⁴⁹ The lecithinase activity occurs at 37° C. and, unlike hemolysis, does not require subsequent chilling. The hypothesis that hemolysis is due to alteration of the erythrocyte membrane by the hydrolysis of contained lecithin is an attractive one but does not account for the necessity of subsequent chilling for hemolysis to occur. However this may be, the α -toxin has been purified by methanol precipitation in the cold and effectively separated from the other toxins of Cl. welchii; lecithinase activity, lethal activity, and hemolytic activity remained proportional, suggesting that all are activities of the same substance, but the preparations were electrophoretically heterogeneous. There is a curious inverse relationship between toxigenicity and the heat resistance and sporulating potency of the bacilli.89

The θ -toxin is sharply differentiable from the α -toxin in that it is an oxygen-labile

hemolysin, *i.e.*, is active in the reduced state, is more rapidly absorbed on sheep erythrocytes in the cold than the α -toxin, and does not require calcium or magnesium for hemolysis and is, therefore, active in the presence of phosphate.

In addition to the α -toxin and θ -toxin, the κ-toxin breaks down muscle by dissolution of its collagen and reticulin structure; the part it plays in the pathology of the infection is not clear. It does not appear to be as important as the α -toxin, for while antiserum to the α -toxin alone is protective, anticollagenase alone is not.2 All the types share with the cholera vibrio the production of myxovirus receptor-destroying enzyme. which in the cholera vibrio and the myxoviruses is neuraminidase, but evidence has been presented that in Cl. welchii it is not identical with neuraminidase.13

In addition to these toxins, there is a non-toxic antigenic substance produced, described by Fredette and his co-workers²⁴ some years ago, called the "bursting factor." It is demonstrable by enhancement of experimental infections, and produces an immunity in the absence of antitoxins.

In general the toxins formed by Cl. welchii appear to account in very large part for the observed histopathology. Robb-Smith, 72 for example, has compared the toxin in naturally occuring infection in man, in experimentally infected animals, and in normal human muscle exposed to the action of filtrates in vitro and found the histopathological changes to be substantially the same in all three.

There appears to be no simple method of typing Cl. welchii, and the presence or absence of the various toxins must be demonstrated. The typing procedure, using monospecific antiserums, is that of Oakley and Warrack referred to above, but strains do not always conform precisely to the general pattern, and cross-neutralization of the toxins may be incomplete.

Pathogenicity for man. Cl. welchii is, perhaps, the most important cause of gaseous gangrene and is found either alone or mixed with other anaerobes in the majority of cases of this disease. Tissue injury is a usual, perhaps essential, preliminary to infection, but once the bacilli are established they invade the surrounding tissue rapidly. They apparently travel along the interstitial tissue of the muscle and are often found beyond the gangrenous area. The large

amount of hyaluronidase produced would seem to be related to this rapid spread, but a number of studies have indicated that there is little or no relation between the invasiveness of *Cl. welchii* and at least *in vitro* titers of hyaluronidase.

Although most commonly found in gangrene, Cl. welchii has also been observed in closed abscesses in uterine infections and in infections of the gastrointestinal, genitourinary, and biliary tracts. It has been isolated from the blood during life, but septicemia is much less common in man than in experimental animals, although blood invasion occurs frequently in man during the agonal period or immediately following death. Study of the "foamy organs" sometimes observed at autopsy has shown that the presence of gas in the internal organs shortly after death is often attributable to an invasion by this microorganism.

Evidence has accumulated that Cl. welchii may be a common cause of food poisoning, ³⁹ similar to food poisoning of other etiology, with an incubation period of 10 to 12 hours, vomiting and diarrhea, and recovery in 24 to 48 hours (Chap. Twelve). It appears to be a foodborne infection with type A, and is unrelated to the necrotic enteritis, or pigbel, acquired from eating pork and found in Papua-New Guinea. The latter disease is a highly fatal one, with a case fatality rate of 50 per cent, apparently caused by type C (or F); serological evidence and antitoxin therapy have suggested that the β -toxin is involved in its pathogenesis. ⁵⁸

Cl. welchii is a normal inhabitant of the human intestine and is constantly present in small numbers; in fact, it has been used to a certain extent in Europe as an indicator of fecal pollution of water. The toxemia of acute intestinal obstruction has been attributed by some to the proliferation of Cl. welchii in the bowel followed by absorption of formed toxin, but it is now clear that such a relationship does not exist. This bacterium is, however, found with some frequency in gangrenous appendicitis, and it has been reported that antitoxin is of value in the treatment of perforative appendicitis.

Since infection with Cl. welchii is frequently characterized by gross blood destruction, jaundice, and anemia, a possible relationship between this bacterium and various anemias has been of some interest A pernicious and fatal anemia may be produced in experimental animals by intratibial

inoculation of culture, or a temporary but severe anemia by inoculation of filtrate. Both natural and experimental infections, therefore, lead to the development of severe anemia which is probably due to the continuous release of the hemolytic toxin.

Pathogenicity for lower animals. Natural infections in lower animals with Cl. welchii types have been referred to above. The occurrence of the gaseous gangrene bacillus, however, is rare; local abscesses have been observed in dogs and rabbits following injury. Experimentally certain strains are pathogenic for guinea pigs, pigeons, and mice, less so for rabbits. If a rabbit or guinea pig is killed a few minutes after intravenous injection of Cl. welchii and the body incubated at 37° C., gas is produced in a few hours throughout the body and the phenomenon of "foamy liver" is reproduced. This phenomenon is not strictly specific for Cl. welchii; it may be produced by similar inoculations with several other anaerobes, though the results are less striking. The pigeon is susceptible and is used for the standardization of toxin and antitoxin; an international standard has been established.21

The classic welchii toxin, the α -toxin, is not a powerful one; the MLD for a mouse is usually about 0.25 ml. of liquid culture. Antitoxins may be produced, which have both prophylactic and therapeutic value, and welchii is included in polyvalent antitoxic serums for gaseous gangrene. Antitoxin to the α -toxin appears to be far more important than that to the θ -toxin. It is difficult to develop agglutinins for Cl. welchii, and an antibacterial immunity does not protect against infection.

CLOSTRIDIUM NOVYI (CLOSTRIDIUM OEDEMATIENS)

The third important anaerobe in gaseous gangrene was probably first discovered by Novy in 1894 in a study of "malignant edema" in guinea pigs, and was designated Bacillus oedematis maligni Nr. II. It was named B. novyi by Migula in 1900. In 1915 Weinberg and Séguin isolated several strains of this bacillus, but first regarded it as a new species and named it B. oedematiens. The French name has been used by European workers.

Cl. novyi is noteworthy not only for its

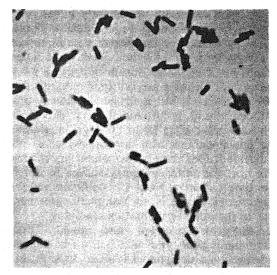

Figure 166. Clostridium novyi from pure culture. The slight tendency to curvature is apparent in some of the vegetative cells. Note the subterminal spores and the absence of large numbers of free spores. Fuchsin; × 1200.

importance in gaseous gangrene but also because of its potent exotoxin, which compares with the toxin of the diphtheria and tetanus bacilli, and for which a correspondingly potent antitoxin can be produced.

Morphology. Novy's bacillus is a large, relatively thick rod, 2.5 to 10 μ in length and 0.8 to 1 μ in breadth, and occurs singly and in chains. In cultures navicular and curved forms are found; in animal transudates the shorter form predominates. Its numerous spiral flagella, which often become tangled in "bouquets," have been emphasized in nearly all the published descriptions. The rod is nonmotile under ordinary conditions of examination, for movement is markedly inhibited in the presence of air. Subterminal spores are produced but sparsely as a rule and best in nonfermentable mediums. The bacillus is gram-positive.

Young colonies in deep dextrose agar have a yellowish, opaque, irregular center surrounded by a delicate corona of short filaments. Later the colony clears; the center becomes cloudy and in 48 hours is surrounded with a corona of tangled filaments. Surface colonies are extremely delicate, flattened, transparent, bluish gray, with irregular contours, and there is slight hemolysis on blood agar.

Physiology. Cl. novyi is a strict anaerobe and grows well at 37° C. in ordinary med-

iums and especially abundantly in the presence of a fermentable sugar. Meat and brain are not darkened; the former may be turned slightly pink or bleached. Gelatin is liquefied, but coagulated serum and egg are not digested. Nitrates are not reduced and indol is not formed, but hydrogen sulfide is produced. Acid is produced very slowly in litmus milk; after 10 to 30 days' incubation a fine flocculent clot appears which is not digested. Dextrose is fermented but lactose is not; the latter property serves to differentiate Cl. novyi from Cl. septicum and Cl. chauvoei. There is not complete agreement as to the other fermentation reactions.

Antigenic structure and toxin. Three immunological types of Cl. novyi have been defined and designated type A, type B, and type C. These correspond to types based on toxin formation (see below). Cl. hemolyticum, the etiologic agent of infectious icterohemoglobinuria of cattle, is considered to be Cl. novyi type D since it shares the β -toxin with the other types. 63

The toxin formed by this organism is the most potent of the gaseous gangrene bacilli toxins; in contrast to Cl. welchii whose filtrates contain 4 to 5 mouse MLD per ml. the lethal dose of Cl. novyi filtrate for the mouse is about 0.005 ml. Lecithinase and hemolysin activity are present, and six components have been identified by Oakley, Warrack, and Clarke.64 These are designated the α -, β -, γ -, δ -, ϵ -, and ζ -toxins, of which the α -toxin is the classic lethal toxin. The α -toxin is associated with a lipase activity which is responsible for the pearly layered colonial morphology. The lecithinase activity is biochemically similar to that of the α-toxin of Cl. welchii, but the lecithinases of types A and B are distinct serologically from one another and from the α-toxin of Cl. welchii. The distribution of the toxins corresponds to the immunological types noted above and is illustrated in the accompanying table from Oakley et al.

Pathogenicity for man. The relatively frequent occurrence of Cl. novyi in gaseous gangrene has been noted earlier. The disease is characteristically a toxemia, although septicemia is not rare. Like Cl. welchii, Novy's bacillus is often a terminal invader. In pure infections there is less tissue destruction than with Cl. welchii or Cl. septicum. The postmortem findings consist mainly in a massive localized edema, with neither

the extensive gas production of the former nor the sanguineous necrosis of the latter.

Pathogenicity for animals. Natural infections due to Cl. novyi have been observed in guinea pigs, cattle, horses, and hogs. There is some evidence suggesting that type B is etiologically related to infectious necrotic hepatitis (black disease) of sheep. Guinea pigs, rabbits, rats, mice, cats, sheep, horses, and pigeons are susceptible to small doses of culture. Subcutaneous, intramuscular, and intravenous inoculations reproduce the disease experimentally. Toxicity and pathogenicity are easily lost; Novy's original strain which still survives in several laboratories, has long since failed to kill experimental animals. This is true also of strains isolated within five to 10 years.

The action of the toxin freed from bacteria is very similar to that of whole cultures. Sublethal subcutaneous doses of toxin or culture produce a peculiar nonhemorrhagic, gelatinous local edema which reaches its maximum in two or three days. It may be followed by small, superficial hemorrhages, after which it is slowly absorbed, leaving a slightly sclerotic scar. Such lesions appear not to form open phlegmons, as in the case of Cl. welchii cultures, and may also be contrasted with those of the vibrion septique and Cl. chauvoei, which, if they appear at all, are always fatal. Washed cultures are harmless.

Antitoxin has been produced in rabbits, sheep, and horses by successively increased doses of toxic filtrates. The antitoxin has prophylactic and, to some extent, therapeutic value under experimental conditions.

and is now represented in several polyvalent American serums for anaerobic infections.

CLOSTRIDIUM HISTOLYTICUM

Among the species of bacteria discovered by Weinberg and Séguin in war wounds, none is of more interest than Cl. histolyticum, so named because of its remarkable liquefying action upon living tissues. It may be somewhat more common in gaseous gangrene than indicated earlier. It has also been recovered from soil and human feces and from poisoned arrows.

Morphology. Cl. histolyticum is a grampositive motile rod, 3 to 5 μ long and 0.5 to 0.7 μ wide, that forms subterminal clostridial spores. In smears from lesions it appears generally in the form of single or paired short rods with rounded ends. The flagella, often more than 20 in number, are peritrichal. Deep agar colonies vary, according to the consistency of the medium, from compact lobulate globules in 2 per cent agar to fluffy semitransparent or even cottony balls in lower concentrations. Surface colonies are minute round dewdrops and are hemolytic on blood agar.

Physiology. Originally described as an obligate anaerobe, *Cl. histolyticum* is capable of a delicate transparent growth upon the surface of meat infusion agar and is perhaps best regarded as a micro-aerophil or as a facultative anaerobe.

This bacillus is actively proteolytic; not only is gelatin liquefied, but meat and brain and coagulated serum and egg are digested. In older cultures a precipitate of tyrosine crystals appears. Nitrates are not reduced and indol is not formed. No carbohydrates are known to be fermented in spite of statements to the contrary regarding dextrose. The action on milk is slow, but after several days a soft clot is usually formed and then slowly digested, and *Cl. histolyticum* is a proteolytic type.

Toxins. ⁵⁹ A number of toxic substances are formed, a lethal and necrotizing α -toxin and several proteolytic enzymes. One of these, the β -toxin, is a collagenase, and another, the γ -toxin is a cysteine-activated enzyme which attacks altered collagen, νiz ., azocoll. ⁶¹ A third, designated the δ -toxin, is a serologically distinct protease.

Pathogenicity. Infection with Cl. histo-

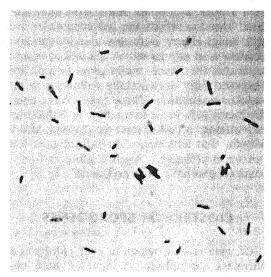

Figure 167. Clostridium histolyticum from pure culture. Note the characteristic short rods with rounded ends and the clostridial subterminal spores. Fuchsin; × 1050.

lyticum alone is probably a rare occurrence: mixed cultures with other anaerobes and aerobes appear to be the rule both in war wounds and in infections observed in horses. Most pure cultures of this bacillus are pathogenic under experimental conditions for rabbits, guinea pigs, mice, and rats, but there is considerable difference between strains. Subcutaneous inoculation of 1 or 2 ml. of a 24-hour broth culture generally produces a local tumefaction followed in 24 to 48 hours by complete sloughing of the overlying skin; then, as a rule, slow healing occurs. Intramuscular inoculation causes swelling, followed by progressive myolysis. If the gluteus muscle of a guinea pig is selected for the inoculation, it may be entirely denuded from the bone within 24 to 48 hours. The tissues literally drip away, and in some cases the limb may be disarticulated. Curiously there is often little or no evidence of intoxication of the animal, but death usually follows through peritonitis due to perforation of the peritoneum. There is occasionally invasion of the blood stream. but generally septicemia does not occur. There is no gas formation in such pure infections.

Bacteria-free filtrates have a lytic action which can be demonstrated if sufficiently large quantities (5 ml.) are injected. The most characteristic effect is the formation of a sterile hematoma filled with uncoagulated blood in which the red corpuscles are still intact. Deep intramuscular inoculation produces an edema which disorganizes and separates the tissue, while gross lesions are observed only occasionally following intravenous inoculation. Three toxins have been distinguished: an α -toxin that is lethal and necrotizing, a collagenase or β -toxin, and a γ -toxin that acts upon altered collagen but not upon collagen. Agglutinating and antitoxic serums have been produced.

CLOSTRIDIUM SPOROGENES

Cl. sporogenes, which in pure culture is a harmless saprophyte, is included here because it is frequently associated with the pathogenic anaerobes in mixed gangrenous infections, very possibly because it is so widely distributed in nature. It has frequently been confused with the pathogenic forms: not only have cultures labeled something else proved to be sporogenes, but there has been a tendency to regard "atoxic variants" or "atoxic strains" of pathogens as Cl. sporogenes. On the other hand, the presence of "atoxic variants" of pathogenic species is in many cases attributable to mixed cultures containing sporogenes. The spores of this microorganism are unusually resistant and invariably survive with those of the pathogens or even after the pathogenic spore-formers are killed in preliminary selective heating.

Morphology. Cl. sporogenes is an actively motile, gram-positive, slender rod, 3 to 7 μ in length and 0.6 to 0.8 μ in breadth, with rounded ends. The cells occur individually, in pairs, in short chains, and sometimes in filaments. The spores are oval, eccentric to subterminal, and swell the vegetative cell. The flagella are peritrichal. The deep agar colonies have the appearance of woolly balls with a dense, compact center. Surface colonies on blood agar are hemolytic, transparent, and usually rhizoid, or ameboid, with a slightly raised center; they appear moist and at first may resemble minute dew drops.

Cl. sporogenes requires strictly anaerobic conditions for growth and will grow upon all the ordinary mediums. It has been cultivated in synthetic solutions containing tryptophan, leucine, tyrosine, arginine, and

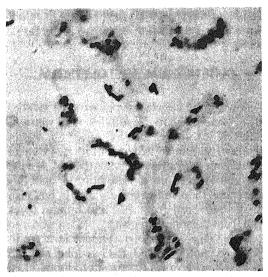

Figure 168. Clostridium sporogenes from pure culture. Note the close morphological resemblance of this species to the pathogenic forms. Fuchsin; × 1050.

phenylalanine, together with an unknown substance termed "sporogenes vitamin." Its optimum temperature is 37° C., but it will grow at temperatures as high as 50° C.

This bacillus is actively proteolytic; it produces blackening and digestion of brain and meat mediums, coagulated egg, and serum. An excess of fermentable sugar delays or inhibits this proteolysis, and the presence of metallic iron or certain iron salts accelerates it. Tyrosine crystals are not obvious. Gelatin is liquefied and blackened, hydrogen sulfide is produced, but indol production is doubtful, and nitrates are not reduced to nitrites. Reports on sugar fermentations are conflicting. According to Bergey, acid and gas are formed from dextrose, levulose, galactose, and maltose, while lactose, sucrose, salicin, and inulin are not fermented. Growth on milk is at first slow; in 48 to 72 hours a clot is formed and progressive liquefaction occurs with abundant gas and acid formation until the casein is completely peptonized.

Pathogenicity. There is no authentic record of a natural infection attributable to Cl. sporogenes alone. It has been claimed that this bacillus is a factor in certain intestinal disorders, but its frequent occurrence in the intestinal tract of healthy men and animals is not consistent with this.

In animal experiments relatively large

doses are required to produce lesions; less than 5 ml. of a young dextrose broth culture injected subcutaneously in guinea pigs, which are the most susceptible experimental animals, usually results in only a local reaction. In a few hours the immediately overlying hair loosens, the skin becomes gangrenous and raised slightly over an area of subcutaneous tissue digestion in which a small amount of gas appears. Such animals usually show no systemic involvement, and the lesion heals in a few days, leaving a necrotic scar which heals slowly. The reaction to intramuscular injection is only slightly more severe.

The most obviously important of the

pathogenic effects of Cl. sporogenes (and probably of other putrefactive anaerobes) is that of a mutual acceleration in metabolism which occurs during growth with the pathogenic anaerobes, especially Cl. welchii, Cl. septicum, and Cl. novyi. While the presence of various aerobes is in some degree stimulating to the growth of obligate anaerobes (due partly, as Pasteur suggested, to the absorption of oxygen, but also to other factors), the presence of putrefactive anaerobes greatly enhances the pathogenicity of the nonputrefactive pathogens. The proteolytic forms supply protein-split products which the fermentative types are unable to elaborate so rapidly.

Clostridium chauvoei (Clostridium feseri)

Blackleg, also known as quarter evil and symptomatic anthrax (not to be confused with anthrax), is an acute disease affecting cattle. It occurs wherever cattle are kept and is prevalent throughout the United States with the possible exception of the Southern Atlantic and Eastern Gulf States. The name blackleg, like gaseous gangrene, has been applied to affections due to various anaerobes; in some instances Cl. septicum or, rarely, Cl. novyi is found, but the principal cause is Cl. chauvoei (Cl. feseri). Just as Cl. welchii (type A) is not involved in natural infections of lower animals, so Cl. chauvoei has never been shown to be responsible for any human infection.

Although the bacilli had been earlier observed and the disease transmitted by the injection of the serous fluid from an infected animal into a healthy animal, *Cl. chauvoei* was cultivated, and its causal relation to blackleg established by Arlong, Cornevin, and Thomas in 1887.

Morphology. Cl. chauvoei is a grampositive, motile, sporulating rod. The size is variable, ranging from 3 to 8 μ in length and about 1 μ in breadth. The cells occur singly as a rule; in contrast with Cl. septicum, there is little tendency to form chains or filaments. The spores are subterminal and oval, swelling the vegetative cell in which they occur. Sporulation is often preceded by a marked swelling of the vegetative cell. Deep agar colonies are minute, compact, and downy. On the surface of blood

agar well-separated colonies are flat, round, or leaf-like, and hemolytic.

Physiology. This bacillus is a strict anaerobe and, like Cl. sporogenes, grows at temperatures as high as 50° C., though the optimum is 37° C. It will grow on the usual laboratory mediums but is best cultivated in meat or brain medium. These are neither discolored nor digested by pure cultures, but they may be slightly softened. Gelatin

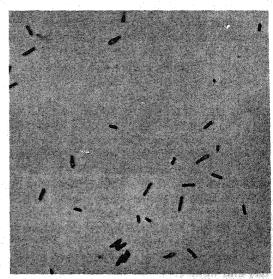

Figure 169. Clostridium chauvoei from pure culture. Subterminal oval spores are apparent; note the swollen presporulating cell on the far right. Fuchsin; × 1050.

is liquefied, but coagulated serum and egg are not. Hydrogen sulfide is produced, but indol is not formed, and nitrates are not reduced to nitrites. Dextrose, levulose, galactose, maltose, sucrose, and lactose are fermented with the formation of acid and gas; inulin, salicin, mannitol, dulcitol, and glycerol are not fermented. It may be noted again that this microorganism may be differentiated from the closely related *Cl. septicum* on the basis of the sucrose and salicin fermentation. Litmus-milk cultures become acid and the casein is precipitated, but peptonization does not occur.

Pathogenicity. Natural infections due to Cl. chauvoei occur principally in cattle. There are still several obscure features in the epidemiology. The disease occurs at special seasons of the year, is connected with certain localities, and is said to show a distinct predilection for the best young stock. The portal of entry is uncertain; whether it enters by way of minute abrasions on the skin or through the gastrointestinal mucosa is quite unknown. Experimentally, Cl. chauvoei is pathogenic for cattle, sheep, goats, guinea pigs, and mice; horses, asses,

hogs, rabbits, rats, and pigeons are somewhat refractory.

The symptoms in animals consist in crepitant localized swellings, which in natural infections occur on the thighs, neck, or shoulders. The animals become stupid, feverish, and anorectic. Treatment is rarely successful, and sick animals usually die in one to two days. The disease is a progressive bacteremia. A weak exotoxin is produced.

Immunization. An effective immunity is produced by inoculation with a formalininactivated whole culture vaccine or with washed bacteria inactivated with calcium chloride. An alum-precipitated toxoid has been used also. The immunity so produced is limited, probably effective little longer than a year, but under natural conditions of exposure to infection may be reinforced to give the appearance of a long-lasting immunity. Unlike most of the other diseases of clostridial etiology, blackleg responds to treatment with antibiotics, and penicillin is most commonly used. A hyperimmune serum may be prepared by immunization of horses with vaccine which is said to have therapeutic value.

Clostridium botulinum

Botulism was first definitely observed in Germany in 1785 and was and is associated though by no means exclusively, with the consumption of sausages; hence the not altogether appropriate name botulism. The causative bacterium was isolated by van Ermengem in 1896 and named Bacillus botulinus. It is now known as Cl. botulinum.

Morphology. Cl. botulinum is a large, pleomorphic, gram-positive, motile, sporulating rod 4 to 6 μ in length and 0.9 to 1.2 μ in breadth. The cells occur singly, in pairs, and in chains. There are four to eight peritrichal flagella. The spores are subterminal and oval and distend the vegetative cells containing them. Spore formation is variable from strain to strain, some strains producing spores abundantly, others sparsely; but in general spore formation is best in sugar-free mediums.

Deep agar colonies are translucent, globular, and diffuse, or flat and heart-shaped or disc-shaped, according to the consistency of the medium. Surface colonies are relatively large, 5 to 10 mm. in diameter, glisten-

ing, translucent at the edges with a thicker brownish center, filamentous, and hemolytic on blood agar.

Physiology. Cl. botulinum may be grown on the usual laboratory mediums under strict anaerobic conditions; cultivation on synthetic solutions has indicated that the amino acids cystine, leucine, lysine, glycine, and proline are required. Amino acids are decomposed by coupled oxidation-reduction reactions rather than by direct oxidation. Brain, meat, and coagulated protein mediums are blackened and digested; gelatin is liquefied. Milk is peptonized. Hydrogen sulfide is produced, but nitrates are not reduced to nitrites, and indol is not formed. Dextrose, levulose, and maltose are fermented; the fermentation of other sugars is variable from strain to strain and type to type. The spores are highly resistant and withstand boiling for 30 minutes to 22 hours, and autoclaving at 120° C. for as long as 20 minutes.

Irrespective of the presence of fermentable sugar, potent soluble toxins are pro-

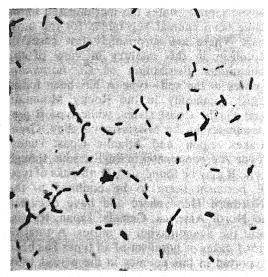

Figure 170. Clostridium botulinum type A from pure culture. Note the subterminal swollen spores and free unstained spores admixed with the vegetative cells. Fuchsin; × 1050.

duced which resemble other soluble toxins in most respects. They are, however, unusually stable to heat; heating to 80° C. for 30 minutes or boiling for 10 minutes is required for destruction. They are also relatively resistant to proteolytic digestion in the intestinal tract, and may be broken down into active fragments which may facilitate absorption from the bowel. In any case, they are unique among the classic bacterial exotoxins in that they are effective by mouth. 43, 44 They are the most potent bacterial toxins known; the guinea-pig MLD may be as small as 1×10^{-6} ml. of broth culture.

Types. Cl. botulinum is subdivided into a number of types which differ from one another in that their toxins are immunologically different. The best known of these are types A and B, which in the past have been regarded as solely responsible for human botulism. It is supposed that van Ermengem's original culture, now no longer available, was type B.

Additional types have been described since the early 1920's. A toxin-producing anaerobic bacillus isolated from fly larvae (the ingestion of which was associated with a paralytic disease of chickens) has been designated type C. A closely related bacillus was isolated from botulism of cattle in Australia which was designated B. parabotu-

linus. This bacillus is now designated Cl. botulinum type $C\beta$ and the fly larvae bacillus Cl. botulinum type $C\alpha$. The toxins of these subtypes of type C are related in that $C\alpha$ -antitoxin protects against both $C\alpha$ - and $C\beta$ -toxin, but $C\beta$ -antitoxin protects against $C\beta$ -toxin but not $C\alpha$ -toxin.

A South African strain first described by Theiler and Robinson, designated by them Cl. parabotulinum equi, was further studied and given the name Cl. botulinum type D, for its toxin is not neutralized by the antitoxins of type A, B, or C. There is some confusion in this nomenclature in that the type designated type D by the French workers corresponds to type C in this country.

Cl. botulinum type E was originally isolated from fish products which had caused human botulism, and outbreaks of human botulism associated with the consumption of fish products have occurred in this country since 1932, and in Canada and Japan. The toxin is immunologically distinct, showing no cross-neutralization by antitoxins to the other toxin types. Still another type, similarly distinct and designated type F, was described in 1958 in Denmark¹⁷ and has been isolated in this country from salmon in the Columbia River.¹⁴

Toxins. As just indicated, a number of immunologically different toxins are produced by Cl. botulinum, and a given toxin is produced by a single type rather than the various toxins being distributed among the types as in the case of Cl. welchii. Furthermore, the pharmacological action of the toxins is essentially the same and differentiation can be made only on an immunological basis, i.e., the passive protection test in which a series of experimental animals is passively immunized, each with a single antitoxin, and all challenged with the unknown toxin.

Of these toxins, that of type A is the most potent, exceeds in toxicity the other soluble toxins such as those of the diphtheria and tetanus bacilli, and is the most potent toxic substance known. All of the botulinum toxins, with the exception of type F, have been prepared in highly purified, or crystalline, form. The LD₅₀ of such preparations of type A and type B toxins contains on the order of 5×10^{-9} mg.N. As prepared, they are polymers having molecular weights of perhaps 1×10^6 , but are now known to represent aggregates of toxic moieties having molecular

lar weights of 10,000 to 12,000.^{26, 27, 28, 38} Both pure and crude botulinum toxins may be detoxified with formaldehyde to give formol toxoid which may be used for active immunization.⁹²

The types of Cl. botulinum are not biochemically or culturally distinguishable, but, as a group, they may be divided into two biochemical types, the one proteolytic (sometimes designated ovolytic but digesting proteins other than coagulated egg albumin), whose cultural characteristics have been described above, and the other saccharolytic or fermentative in character, whose members do not hydrolyze coagulated native proteins. The proteolytic group includes type A and some strains of type B (the majority of the American type B strains are proteolytic, while a great many of the European type B strains are not). The nonproteolytic group includes some strains of type B, and, so far as is known, all strains of types C, D, and E. It has been suggested that only the nonproteolytic varieties be designated Cl. botulinum and that the proteolytic varieties be termed Cl. parabotulinum.

Pathogenicity for man.⁵⁴ Human botulism is almost invariably the result of eating preserved foods in which the bacillus has grown and produced toxin. In Europe most cases have been due to the consumption of various kinds of preserved meats, such as sausage, ham, potted goose, or duck, while

in the United States the incriminated foods have been canned vegetables for the most part. There are surprisingly few cases of botulism in this country in view of the ubiquitous distribution of Cl. botulinum spores in the soil-type A has been found most commonly in the Rocky Mountain and Pacific Coast states, while type B predominates in the Mississippi Valley, Great Lakes region, and Atlantic Coast states. Type A predominates in English soils, though type B may be found also. Outbreaks of type E botulism seem to be confined to the Northern Hemisphere and have occurred in North America, Canada, Japan, Russia, and the Scandinavian countries. A total of 1561 cases of botulism of all types has been reported in this country in the period 1899 to 1963.66 The incidence is generally low; it rose to a peak of 23 outbreaks in 1922, declined, and rose again to a peak of 26 in 1935, and has since remained relatively high but with some tendency to fall.

Type E botulism has been associated with the consumption of fish and fish products. A preparation of raw fish, izushi, has been the vehicle in Japan, where 304 cases in 49 outbreaks were reported between 1951 and 1962.86 Outbreaks have occurred in Canada.16 In this country an outbreak in 1963 due to the consumption of canned tuna fish was the first instance of botulism from commercially canned foods in 40 years.41

Figure 171. The reported cases of and deaths from botulism in the United States during the period 1950-1965. (Morbidity and Mortality Weekly Report, Annual Supplement, Vol. 14, No. 53, Communicable Disease Center, Public Health Service, U. S. Department of Health, Education, and Welfare.)

Types of Clostridium botulinum

ТҮРЕ	SYNONYM	BIOCHEMICAL CHARACTER	DISEASE	ANTITOXIN
Α		Proteolytic	Botulism of man, limberneck of chickens	Specific
B		Some strains proteolytic	Botulism of man, limberneck of chickens	Specific
Сα	Fly larvae bacillus	Nonproteolytic	Paralytic disease of chickens, botulism of wild ducks	Neutralizes Cβ-toxin
Сβ	Cl. parabotulinum	Nonproteolytic	Forage poisoning of cattle (Australia)	Specific
D	Cl. parabotulinum equi	Nonproteolytic	Lamziekte of cattle (Africa)	Specific
E		Nonproteolytic	Botulism of man	Specific
F		Proteolytic	Botulism of man	Specific

Smoked fish, consumed essentially uncooked, from the Great Lakes have also produced human botulism, and the incidence of the microorganism in the intestinal contents of fish has ranged from 1 per cent in Lake Superior to 4 per cent in Lake Huron, 9 per cent in Lake Michigan, and 57 per cent in Green Bay (on Lake Michigan). Whether such contamination represents a reservoir of infection or incidental contamination from soil is not known.

As in the case of the other sporulating anaerobes, the disease produced by Cl. botulinum is an intoxication; in botulism, in fact, there is no invasion of the tissues and the toxin is preformed outside the body. Under experimental conditions in which massive doses of spores have been injected, it is probable that no infection has been set up. Cl. botulinum has, however, been found in contaminated wounds in mixed culture with aerobic and anaerobic bacteria. Under rare circumstances, then, it may proliferate in the tissues. In a group of three cases there were no symptoms of botulism, but in three fatal cases in which type A was found, symptoms of botulism were present. 15, 33, 34, 87

Human botulism is most commonly caused by types A and B. The pharmacological activity of these toxins seems to be substantially identical, and the mechanism of their action has been of considerable interest. Acetylcholine produces contraction of botulinum-poisoned muscle, but not of curare-poisoned muscle. In the poisoned animal, apparently acetylcholine is not produced in the end plates, and the action of the toxin is proximal to the point at which

it is produced. It has been found that the activity of the toxin is on the nerve filaments since acetylcholine is released following direct stimulation of the excised diaphragm of the guinea pig, but not following tetanization of the phrenic nerves. The evidence suggests that the neuromuscular paralysis observed in the poisoned animal is a result of interference with conduction in the terminal twigs of motor nerves, near or at the points of final branching, but proximal to the site of acetylcholine release.8,83 In man paralysis of the motor nerve end plates in the striated muscles and diaphragm is produced, and the symptoms include vomiting, constipation, ocular paresis, and pharyngeal paralysis.

Death may occur within a day of the onset of symptoms or may be delayed for as long as a week. At autopsy the liver, kidneys, and meninges are congested, and there may be thrombosis. The case fatality is variable; in this country it has been 60 to 70 per cent but lower in Germany, perhaps 25 per cent, possibly owing to the greater prevalence of the somewhat less toxic type B.

Pathogenicity for lower animals. Associated with human cases of botulism there have been numerous outbreaks of limberneck, a paralytic disease, among fowls fed the toxin-containing food. Other forms of botulism in lower animals occur under natural conditions. Cl. botulinum types C and D appear to be associated exclusively with the disease in lower animals. Certain forms of forage poisoning in cattle and horses in Australia are botulism, but whether the bacilli grow and form toxin in the fodder or whether the disease results from the

ingestion of rabbit carrion is not entirely clear. The South African disease of cattle, lamziekte, is botulism resulting from the ingestion of contaminated carrion. In the United States botulism of wild ducks and other waterfowl due to type $C\alpha$ is prevalent and causes the death of thousands of ducks each year. The source of the toxin ingested by these fowl is uncertain.

Experimentally rabbits, guinea pigs, mice, monkeys, cats, and dogs are susceptible to toxin administered parenterally or per os. The symptoms are similar to those of naturally infected animals and of man, and the postmortem findings are much the same. Experimental animals vary widely in their susceptibility to the toxins of the various types of Cl. botulinum.

Immunity. Formol toxoid may be used as an immunizing antigen to produce an active immunity with circulating antitoxin present in the blood. Such active immunization has been carried out in lower animals when economically feasible; in Australia botulism of sheep and cattle has assumed sufficient proportions to justify such active immunization, and it has been applied on a small scale.

Man may also be immunized with fluid or alum-precipitated toxoid of type A or type B or a mixture of both types. With an immunization schedule of 0-2-10 weeks, the arbitrarily defined protection level of 0.02 units of type A and 0.005 units of type B antitoxin per ml. of circulating blood is reached in 50 per cent of those inoculated in about three months after initiation of the immunization. Booster inoculation at one year raises the titer 500-fold the minimal protective level, and the high titer persists for at least two years.22 Under ordinary circumstances naturally occurring botulism in man is so rare that active immunization is not worth while.

Botulinum toxin is an excellent antigen, and high-titer antitoxic serums may be produced. International standards for the antitoxins have been described. Under experimental conditions these antitoxins have marked prophylactic value, but their therapeutic efficacy is slight. It may be pointed out that in botulism, as in tetanus, the symptoms are a consequence of the injury to the nerve tissue, and the administration of antitoxin serves only to neutralize circulating toxin. The almost complete leck of therapeutic effect of botulinum antitoxin in hu-

man botulism is undoubtedly attributable to the inevitable too-late administration.

CORYNEBACTERIUM (THE DIPHTHERIA BACILLUS)

As a clinical entity diphtheria dates from the observations of Bretonneau in 1826. The diphtheria bacillus was observed and described by Klebs in 1883, but its etiological relation to the disease was suggested by the investigations of Löffler the following year. Löffler isolated the bacillus observed by Klebs in pure culture from a number of cases of diphtheria but expressly disclaimed the assumption that his bacillus was the causal agent of diphtheria, in part because he found it in the throat of a healthy child, and in part because he did not find it in all cases of what were apparently clinical diphtheria. The significance of Löffler's findings is now clear, however, for it is known that other bacteria, such as streptococci, can produce a condition in the throat closely resembling diphtheria and that the diphtheria bacillus may be present in the throat as well as in the nose in the carrier state. Further investigations by other workers indicated that the Klebs-Löffler bacillus was always present in the typical false membrane of diphtheria. In 1888 Roux and Yersin showed that this bacillus formed a soluble toxin which reproduced the characteristic symptoms and lesions of diphtheria and this demonstrated its etiological relation to the disease.

Morphology and staining.²⁰ The diphtheria bacillus is a slender rod ranging from 1 to 6 μ in length and 0.3 to 0.8 μ in breadth. The bacilli are highly pleomorphic, for, in addition to the straight or slightly curved rods, club-shaped and branching forms are not infrequently observed. Septa in the cell and the occurrence of branched forms are readily apparent in the living cell examined by phase microscopy. The presence of the latter, which are a consequence of true

branching, is indicative of the close relation of the diphtheria bacillus to some of the higher fungi. Upon completion of cell division a movement designated as snapping occurs, and the bacilli may remain attached but at sharp angles to one another.

The diphtheria bacillus tends to stain irregularly. Some cells stain solidly, others take the stain more deeply in transverse bands to give a barred appearance, and in still others deeply staining metachromatic or Babes-Ernst granules are found. A single cell may contain from one to generally not more than five or six such metachromatic granules; they may be found at one or both ends of the cells, particularly those with swollen ends, and when more than two are present the remainder are scattered within the cell substance. This irregular staining is apparent with Löffler's alkaline methylene blue or with toluidine blue.¹²

In stained smears the appearance of diphtheria bacilli is highly characteristic. They may not be identified on morphological grounds alone, for many of the pseudodiphtheria bacilli or diphtheroids also stain irregularly and are similarly pleomorphic. It was formerly thought that there was an association between morphological type and virulence. At present little emphasis is placed upon morphology in this connection, though in a general way granular types seem to predominate in clinical diphtheria, and there appears to be a rough association between morphological type and the mitis and gravis types, as will appear. The diphtheria bacillus is gram-positive but decolorizes more readily than most of the gram-positive bacteria.

Surface colonies on Löffler's serum medium or on agar are small and gray; when

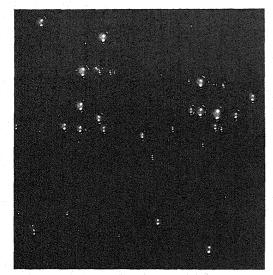

Figure 172. Colonies of Corynebacterium diphtheriae on blood agar. Note the smooth, raised, translucent appearance and relatively small size. × 2.

viewed under low magnification they are found to be coarsely granular and somewhat irregular in outline, with ragged or fringed edges. On differential mediums containing potassium tellurite, colonies of the diphtheria bacillus are dark gray or black because of reduction of the tellurite and are readily differentiated from those of contaminating bacteria. Tellurite reduction apparently occurs within the bacterial cell. Microscopic morphology may not be characteristic in smears made from tellurite medium cultures.

Physiology. The optimum growth temperature for the diphtheria bacillus is 34° to 36° C., and it grows well at 37° C.; growth will take place over the range from 15° to 40° C. An alkaline reaction is required, pH 7.8 to 8.0, and free access to air is essential, for growth under anaerobic conditions is sparse.* Growth and toxin production occur in aerated bulk, e.g., "submerged," culture in tanks.¹⁴

In primary isolation the diphtheria bacillus is best cultivated on enriched mediums. Growth is rapid on Löffler's serum medium (three parts of beef or sheep serum and one part of 1 per cent dextrose broth coagulated in slant form by inspissation), and minute but visible colonies appear after 12 to 24 hours' incubation. In recent years a variety

of differential and selective mediums have been introduced, all of which contain potassium tellurite. The better known of these are the chocolate agar-tellurite medium of Anderson and his co-workers, which has been subject to minor modifications by a number of other workers, such as Neill's medium and Hovle's medium which are used in England, and the various mediums developed by Clauberg, whose inspissated serum-glycerol-tellurite medium has been widely tested. There is general agreement that the proportion of positive cultures is somewhat higher with the Clauberg medium than with Löffler's medium; whether the heated blood-tellurite mediums are superior to Löffler's medium is not clear. As indicated above, the characteristic morphology of the diphtheria bacillus is not always seen in smears from colonies on tellurite mediums, and, therefore, in some laboratories both Löffler's medium and a differential tellurite medium are inoculated and the former used for microscopic examination if typical colonies appear on the differential medium.

The diphtheria bacillus can be cultivated on ordinary nutrient and infusion mediums. Growth is somewhat scanty on the former but good on the fresh meat infusions. Some strains, including the well-known Park 8, may be cultivated on synthetic solutions

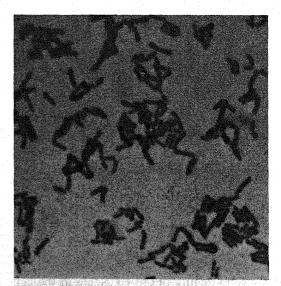

Figure 173. The diphtheria bacillus, gravis strain, pure culture on blood agar. Note the bipolar staining and the club-shaped forms. The lightly stained cells with deeply stained areas are characteristic of gravis morphology. Methylene blue stain; × 1200.

^{*}Strains of virulent diphtheria bacilli which grow more luxuriantly under anaerobic conditions than in the presence of air have been reported.

containing a number of amino acids together with small quantities of nicotinic acid, β -alanine, or pantothenic acid, and pimelic acid. It has been suggested that pimelic acid is utilized by this bacterium for the synthesis of biotin, since growth is stimulated by biotin in the absence of pimelic acid. Recently isolated strains also require oleic acid for development, especially if the inoculum is small. Nutritive requirements differ somewhat from one strain to another, and a general statement is not possible.

The diphtheria bacillus does not liquefy gelatin or digest coagulated protein. Indol is not formed,* nitrates are reduced to nitrites, and hydrogen sulfide is formed. All strains form acid but no gas from dextrose and levulose, and some strains ferment dextrin, glycogen, starch, galactose, maltose, and glycerol. There appear to be no well-defined biochemical groups among these bacilli. The fermentation of dextrose is of some interest in that propionic acid is formed. Other products of the fermentation include lactic, acetic, formic, and succinic acids and ethyl alcohol.

In ordinary culture mediums the diphtheria bacillus may remain viable for relatively long periods. It will live six to eight weeks on agar, five to six months on blood serum, 12 to 15 months on dextrose blood serum, and as long as three months in particles of diphtheritic membrane. Although virulence is ordinarily reduced by continued culture on laboratory mediums, some strains remain fully virulent, *i.e.*, toxigenic, on prolonged cultivation. The bacilli are unusually susceptible to heat; a suspension or broth culture is killed by holding at 58° C. for 10 minutes. In diphtheritic membrane they are considerably more resistant.

Antigenic structure. Although the diphtheria toxin (see below) is apparently immunologically identical in all strains, the diphtheria bacilli are heterogeneous with respect to cell antigens. They tend to agglutinate spontaneously, which may be partially countered by using 0.5 per cent saline as the suspending medium, but agglutinative types may be determined. They contain heat-stable somatic antigens which appear to be polysaccharide in nature, and heat-labile protein somatic antigens. The former have

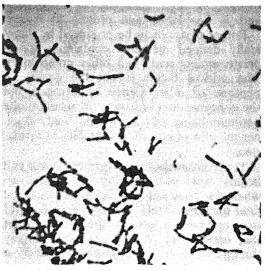

Figure 174. The diphtheria bacillus, intermedius strain, pure culture on blood agar. Note the irregular staining and barred appearance characteristic of the intermedius variety. Methylene blue stain; × 1200.

little differential value, and the agglutinative types which have been described depend upon the protein antigens.²⁴ There is some correlation between agglutinative types and the *mitis-intermedius-gravis* colonial type¹⁹ (see below), but such agglutinative types have little significance to the disease, although antibacterial immunity is considered by some to be a possible element in effective immunity (see below).

Toxin. With the exception of the Shiga dysentery bacillus, the diphtheria bacillus is the only aerobic bacterium that produces an exotoxin comparable to those formed by the sporulating anaerobes. Filtrates from broth cultures are not so toxic as those of the tetanus and botulinus bacilli; exceptionally potent filtrates may contain as much as 1000 guinea-pig MLD's per ml. Virulence is synonymous with toxigenicity, and the various virulence tests are tests for the formation of toxin.

The production of toxin is markedly influenced by environmental and nutritive conditions. A slightly alkaline reaction, pH 7.8 to 8.0, is essential; an acid reaction inhibits toxin formation. Free access to air is also necessary, and for the production of toxin the bacilli are cultivated in thin layers of beef infusion broth. Maximum amounts of toxin are found after seven to 10 days' incubation at 36° to 37° C. The toxicity is

^{*}The test with sulfuric acid and potassium nitrite may be positive because of the formation of indolacetic acid, but no color is produced with Ehrlich's reagent, p-dimethylamidobenzaldehyde.

unstable to slight acidities, pH 6.0 or less, and is heat-labile and protein in nature.

Potent toxins may be produced in chemically defined mediums containing appropriate amino acids and other compounds. The critical factor is not the quality of peptone or other source of nitrogen, but the concentration of iron in the medium; the optimum being $0.14~\mu g$. per ml., and $5.0~\mu g$. per ml. almost completely inhibits its formation

Toxin production lags behind growth and begins rapid accumulation in the medium when the bacterial population has reached near maximal levels, and concentrations of iron optimal for growth are in excess of that optimal for toxin production. Largely through the work of Pappenheimer,36 a close relationship between cytochrome b and the succinoxidase system, and toxin formation has been established. Four mols of porphyrin and one mol of toxin disappear for every four mols of iron over the optimal concentration for toxin production. It is implied, on the one hand, that the toxin may be the protein moiety of an iron-porphyrin enzyme, and on the other, experimental evidence obtained from study of the metamorphosis of cecropia silkworm larvae has suggested that the toxin may interfere in the synthesis of such respiratory enzymes. The hypothesis is attractive and plausible, but as yet lacks supporting evidence for mammalian systems.

The toxin has been prepared as a crystalline protein and subjected to intensive investigation by Pope and Stevens.³⁹ This material is not immunologically homogeneous as indicated by the presence of agglutinin in homologous antibody whose removal by absorption did not affect antitoxic activity. Heterogeneity is also indicated by application of the gel-diffusion technique, and two antigens, in addition to that of the neurotoxin, are demonstrable and are also characterized by resistance to alkaline phosphate and pepsin.

Toxicity. The diphtheria toxin is a potent poison, though not as potent as the botulinum toxins, and is primarily a neurotoxin. Highly pruified preparations have a molecular weight of about 72,000, and the lethal dose for the guinea pig is about 1 μ g. Owing to unfortunate mistakes in the preparation of diphtheria prophylactics, it is known that about 12 guinea-pig MLD's are sufficient to kill a child. The dose-response curve in

the guinea pig is very steep, so much so that the minimal lethal dose assay, adopted many years ago and persisting to the present, is practical.

The pharmacological activity of the toxin is characteristic, and the essential features of the disease are reproducible experimentally with the toxin alone. It produces degenerative changes in the heart muscle, kidneys and liver, and peripheral nerves. The pathology in the adrenals is accentuated and characteristic in the guinea pig. The immediate cause of death in the acute disease is heart failure, and damage to peripheral nerves accounts for the post-diphtheritic paralysis observed in man, and in guinea pigs receiving near-fatal doses of toxin.

Diphtheria toxin is an excellent antigen and gives rise to high titer antitoxic serums. Like the other exotoxins, it is converted to an immunogenically potent toxoid by treatment with formaldehyde.

Lysogenicity and toxigenicity.4 The observation that virulent, i.e., toxigenic, diphtheria bacilli are lysogenic (Chap. Four) and that some nontoxigenic diphtheroid bacilli could often be made toxigenic by conversion to the lysogenic state, was made by Freeman in 1951, and has been studied by a number of workers.⁵ It was found by Hewitt that temperate phages producing lysogenic toxigenic diphtheria bacilli could be of heterologous origin, i.e., staphylococci, and this significant observation has been extended by others. Toxigenicity seems not to be a physiological character transmitted phage-mediated transduction (Chap. Seven); it is possibly an expression of an altered metabolism, perhaps porphyrin metabolism, but as yet studies have been almost exclusively genetic rather than physiological. In any case, it is of interest that some 60 years after the etiology of diphtheria had apparently been fully established, it became evident that more than one microorganism is concerned.

The epidemiological implications are obvious, but are as yet unexplored. Thus the spread of the disease may be covert in some instances in the sense that it may depend in part on the dissemination of the appropriate phage, possibly carried in part by other bacteria such as staphylococci. In this connection it has been observed that there may be a geographical distribution of such phages.¹⁸

Variation. As in other groups of bacteria, smooth and rough variants of the diphtheria bacillus have been observed, and the type of colony formation has been found to be correlated with morphology and virulence; the S variant is the more virulent and the form commonly found in acute cases of diphtheria. Morphological and biochemical variation observed in the diphtheria bacilli has been critically reviewed by Morton.³²

Types²⁸ Morphological types of the diphtheria bacillus were described by Anderson and others in England in 1931 and since have been found in various parts of the world. These were of very considerable interest when first observed for there appeared to be an association, especially in England, between the type and the degree of severity in the clinical manifestations of the disease. Those designated as the gravis and intermedius types were found in severe cases of diphtheria, and the mitis type in the milder cases. The association was less clear on the Continent, and there appeared to be little or no relation in the United States, where the mitis type occurs much more frequently and perhaps only 1 per cent of the strains are of the gravis type.

The toxins produced by the three types are equally neutralizable by the ordinary antitoxic serums, but the *mitis* strains produce toxin somewhat more actively *in vitro* then the *gravis* and *intermedius* types. The three types also appear to be equally virulent for the guinea pig. By now it is more or less

generally agreed that the differentiation of these types is not significantly related to clinical severity but has been useful from an epidemiological point of view.

These types may be differentiated by their colonial form on tellurite mediums. The gravis type produces irregular striated colonies predominantly gray in color; the mitis type produces small, round, smooth, convex colonies predominantly black in color and softer in consistency; and the colonial form of the intermedius type lies between these. Colonial differences are also apparent on certain other mediums, such as trypsin-serum agar and a potato extractcystine-water blue-glycerol medium devised by Clauberg. On fresh blood agar the mitis type is usually hemoltyic, the intermedius type nonhemolytic, and the gravis type usually nonhemolytic. A further distinction is the fermentation of glycogen and starch by the gravis type, but other biochemical tests do not differentiate these types.

There is some association between colonial type and the morphology of the bacillary forms. Those of the gravis type show one or two deeply staining areas, the remainder of the cell staining very lightly; metachromatic granules are seldom observed. Bacilli of the mitis variety stain irregularly and contain very many well-developed metachromatic granules. The intermedius forms have the familar barred appearance. Whereas some 80 per cent of

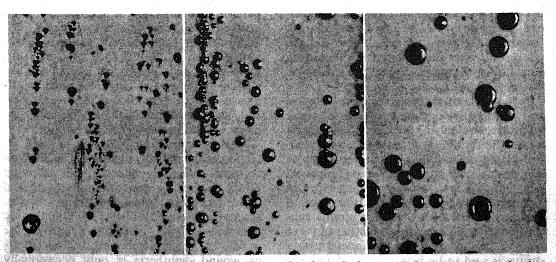

Figure 175. The varieties of the diphtheria bacillus on chocolate tellurite agar. Left, mitis type; note the characteristic raised, small black colony. Center, intermedius type; the lighter color, beginning radial striation, and small size are apparent. Right, gravis type; the gray color, larger size, raised center, and radial striation are evident.

Characteristics of the Diphtheria Bacillus Types

X	TYPE		mitis	intermedius	gravis
	Microscopic		Usually long, with many metachro- matic granules – 80 per cent typical	Usually barred, club forms common— 80 per cent typical	Short, evenly staining – 50-60 per cent typical
Morphology		Tellurite	Small, round, smooth, convex, black with grayish periphery	Small, flat, dull, gray, raised center	Large, irregular, dull, gray, raised center, radial striations
	Colonial	Chocolate Broth	Smooth, semiopaque, glistening Uniform turbidity, sometimes slightly granular, soft pel- licle	Flat, dry, opaque, slight greenish zone Finely granular turbidity	Flat, dry, matt, opaque Granular, flakes, pelliclevariable
Physiology	Fermen- tation of	Glycogen Starch			+
Immunology	Hemolys	is	+ Heterogeneous	Relatively homogeneous	± Two main types

the intermedius variety conform to this morphology, only 50 to 60 per cent of the gravis strains are typical, the remainder resembling the mitis and intermedius forms. Furthermore, 5 to 20 per cent of the mitis strains show barred forms.

Serological investigation has shown that, while these three types are antigenically distinct from one another, the types are not necessarily homogeneous. The mitis strains are heterogeneous, the gravis strains fall for the most part into two types, and the intermedius strains are relatively homogeneous, some strains showing relationship to the gravis types.

Not all strains showing the morphological and biochemical characteristics of these types are virulent, i.e., toxigenic, diphtheria bacilli. Since the diphtheria bacillus is differentiated on the basis of the formation of immunologically specific toxin, it is apparent that mitis, gravis, and intermedius types of diphtheroid bacilli occur. Furthermore, a certain proportion of toxigenic strains cannot be allocated into one or another of these types. The proportion of indeterminate strains is said to be higher when diphtheria is mild.

primarily a disease of childhood, and the age incidence is an expression of waning passive immunity of maternal origin and the development of an active immunity on the one hand, and the risk of exposure on the other. The very young child is passively protected and not exposed to great risk of infection, but by school age the immunity has disappeared in large part and risk of exposure to infection is tremendously increased with entrance into school. The adolescent and adult have acquired an active immunity as a consequence of clinical or, more commonly, inapparent infection. Thus clinical diphtheria is most common in the five to 14 age group, though the carrier state and inapparent infection are probably no more so than in the higher age groups.

Diphtheria in man is usually a local infection of the mucous surfaces. The pharvnx is most commonly affected, but infection of the larynx, or membranous croup, and nasal diphtheria, or membranous rhinitis, are not infrequently observed. Diphtheritic infections of the conjunctiva and of the middle ear are less common, and cutaneous or wound diphtheria is only occasionally observed.

Pathogenicity for man. Diphtheria is The last may assume considerable pro-

portions under certain circumstances. Ulcerative diphtheria of the skin, sometimes called desert sore or tropical ulcer, has been observed in epidemic form in Haifa, and ulcers of the deep, punched-out type occurred in troops living under combat conditions in the south and central Pacific areas during World War II.2, 21 Infection of the mucous surfaces of the genital organs is occasionally found. The invasion of other localities is rare; primary infection of the lungs and diphtheritic meningitis have been observed, and infection of the umbilicus in the newborn has been reported.

Diphtheria bacillus septicemia is occasionally observed, and the suggestion frequently occurs in the German literature that generalized infection with the diphtheria bacillus occurs more often than is generally believed.49 A few cases of acute vegetative endocarditis caused by the diphtheria bacil-

lus have been reported.37

The chief local consequence of infection is a degeneration of the epithelial cells, extending to the underlying tissues and accompanied by a profuse fibrinous exudation, and the characteristic diphtheritic membrane, containing fibrin, dead tissue cells, leucocytes, and bacteria, is formed on the affected surface. The mechanical interference of the membrane with breathing may assume significant proportions and even necessitate intubation or tracheotomy.

Although diphtheria toxin undoubtedly plays a part in the formation of the membrane, its systemic effects following absorption are by far the most important, and diphtheria is, like tetanus, essentially a toxemia. The organs most severely affected are the kidneys, heart, and nerves. A variety of lesions may be found in the kidneys, acute interstitial nephritis being the most common. The lesions in the heart consist commonly of a fatty degeneration in the muscle fibers, which may be very extensive. The diphtheritic myocarditis occurring as a complication usually, but not invariably,9,43 leaves no permanent damage. Fatty degeneration also occurs both in the myelin sheath of the peripheral nerves and in the white matter of the brain and cord. These changes in muscle and nerve account for the serious cardiac weakness often observed in diphtheria and the frequent occurrence of the more or less extensive paralysis which so commonly follows an attack of the disease. It is probable that a small amount of toxin can cause extensive damage in these tissues.

Pathogenicity for lower animals. Diphtheria is not a natural disease of lower animals. Both the local and general symptoms of human diphtheria in man can be reproduced in experimental animals. Inoculations upon the healthy mucous membrane of most adult animals lead to no changes, but if young animals are injected intratracheally, or if the mucous surface is injured before inoculation, a characteristic false membrane is produced which is histologically identical with that found in man.

The subcutaneous inoculation of a guinea pig with a sufficient amount of a young broth culture or toxic filtrate will produce death in one to four days, the time depending upon the size of the inoculum. The animal becomes obviously ill 12 to 18 hours after inoculation, and nephritic symptoms, paralytic manifestations, and other characteristics of human diphtheria are often observed. Postmortem findings include edema and possibly necrosis at the site of inoculation, congestion of the regional lymphatics and abdominal viscera, a pleural exudate, and, characteristic of diphtheritic toxemia in this animal, an enlarged and hemorrhagic condition of the adrenals. As a rule, the bacilli remain localized and are not found in large numbers in the internal organs of the infected animal. Guinea pigs that receive smaller doses and do not die by the fourth day may develop paralytic symptoms and cachexia and die later on, a condition obviously different from the acute toxemia.

Animals vary considerably in their susceptibility to infection. Rats and mice are relatively refractory; rabbits are less susceptible than guinea pigs; cats, dogs, young chicks and pigeons are highly susceptible. Paralytic manifestations appear more frequently in dogs and pigeons than in guinea pigs or rabbits and may be produced in the relatively refractory rat.1

Toxin assay. Assay of toxicity is most commonly carried out in the guinea pig17 and by intradermal inoculation in the rabbit (see below); the latter is considerably more sensitive and dependent upon a local rather than a lethal response. The baby chick is uniformly susceptible to the toxin, dying within 24 hours, and its use has been urged by a number of workers. 10, 23 The toxin is also active against various kinds of cells in culture, and tissue cultures may be used

to assay the activity.^{26, 38, 44} Any such assay may be made use of in the virulence test for toxigenicity and/or applied to the titration of antitoxin.

Bacteriological diagnosis. To establish a diagnosis of infection with diphtheria bacilli, in either case or carrier, the bacillus must be isolated and its toxigenicity demonstrated. The specimen is taken on a swab, either plain or previously dipped in sterile horse serum which is coagulated on the surface by twirling in a flame. It is best to inoculate two mediums, Löffler's serum agar and a tellurite medium such as chocolate tellurite agar; if only a single medium can be used, tellurite is preferable. A blood agar plate should be inoculated as well, both for the isolation of diphtheria-like colonies and to provide for the cultivation of hemolytic streptococci which may be present. After the plates have been inoculated a smear may be made by rolling the swab on a slide, and stained with alkaline methylene blue; it will serve to show the presence of the spirochetes and fusiform bacilli of Vincent's angina should these be present.

Diphtheria bacilli grow up in 18 to 24 hours' incubation. If the characteristic black or gray colonies appear on tellurite, smears may be made from such colonies and from the Löffler slant for microscopic examination; the morphology of the diphtheria bacillus is frequently not characteristic on tellurite, as indicated above. It is often inferred that only diphtheria bacilli grow as black colonies on tellurite medium. This is not true, for any bacterium that reduces tellurite will produce similar colonies; tellurite-reducing bacteria, other than diphtheria bacilli, from the nose and throat are usually staphylococci or micrococci, and as a rule their colonies resemble those of the mitis variety, of diphtheria bacillus but are blacker. Identification in fluorescent antibody-stained smears, of cultures or clinical material, has been described,29 but does not differentiate between toxigenic and nontoxigenic bacilli.

The virulence test. If morphologically typical bacilli are found, toxigenicity must be tested by animal inoculation. This is ordinarily carried out in the guinea pig by subcutaneous or intracutaneous inoculation. In the first instance the growth from a Löffler slant is suspended in 10 ml. saline, and 4 ml. is injected subcutaneously into each of two guinea pigs, one of which has

received 250 units of diphtheria antitoxin 24 hours previously. The diphtheria bacillus will kill the unprotected pig in three to five days, and autopsy will show local edema and the characteristic hemorrhagic enlarged adrenals, while the protected animal will survive. For the intracutaneous test the growth from a Löffler slant is suspended in 20 ml. saline, and 0.15 ml. is injected into the shaved abdominal skin of each of two pigs as above. Toxigenicity is indicated by the development of a local infiltrated lesion which shows superficial necrosis in two or three days in the unprotected pig. By the latter technique a number of tests may be carried out in the same pair of animals.

The virulence test may also be carried out in the rabbit. The growth from a Löffler slant culture is suspended in 2 to 3 ml. of sterile infusion broth, and 0.1 ml. is injected intradermally. Four hours later the animal is given 1000 units of antitoxin intravenously, and immediately afterwards a second intradermal inoculation of 0.1 ml. of the bacterial suspension is made at a site adiacent to that of the first inoculation. Reactions should be read at 72 hours. If the strain of bacteria is toxigenic, the site of the first inoculation will be a central necrotic area, usually hemorrhagic, surrounded by a zone of erythema. The inoculation of antitoxin does not affect a reaction to the first inoculation, but does specificially inhibit a reaction to the second inoculation, and the site of the latter appears as a small, pinkish papule. Eight to 10 such virulence tests may be carried out simultaneously in the same animal.

As indicated above, toxigenicity, or virulence, may also be assayed in other animals, but such virulence tests have not been generally used. An *in vitro* virulence test based on the gel-diffusion technique has been widely applied. It consists essentially in growth of the bacterial strain under consideration on an agar plate in which antitoxin has been placed in a well or trench in the agar medium. The toxin diffusing from the growth forms a line of specific precipitate with the antitoxin diffusing from the reservoir. It is necessary to include a known toxigenic strain for control purposes.

Immunity. Immunity to diphtheria resulting from recovery from a frank attack of the disease, a subclinical infection, or prophylactic inoculation, is essentially an antitoxic immunity, i.e., an immunity to the

disease rather than the infection. Although the toxin is of overriding importance, there is evidence that other toxic substances formed by diphtheria bacilli may contribute to the pathogenesis of the disease, 11 and the question of the significance of an antibacterial immunity is one of perennial interest. 8, 16, 25 The latter is complicated by the serological heterogeneity of the diphtheria bacilli noted above. Effective immunity is, however, generally considered to be primarily antitoxic in nature.

Titration of antitoxin. Assay of antitoxin is based on its specific reaction with a standardized toxin. The classic methods of assay in the guinea pig, described elsewhere (Chap. Fourteen), permit the quantitation of antitoxic activity on the basis of an arbitrarily defined unit. This is necessarily a reflection of a defined dose limit of toxin, the L₊ dose, based on death of the guinea pig, and the Lr, or reactive, dose determined by intradermal titrahon. Since the toxin consists of both toxin and toxoid. a standard antitoxin must be used to define a standard toxin reagent, and the toxin so standardized is, in turn, used to assay the unknown antitoxin in units of activity.

The proportions of toxin and toxoid in a given preparation do not affect its specific reaction with antitoxin in vitro, and either toxin or antitoxin may be titrated against a standard by specific precipitation in the flocculation test. This consists of a determination of the zone of optimal proportions, and the diphtheria toxin-horse antitoxin is the classic system in the so-called H type of flocculation reaction (Chap. Fourteen). In practice flocculation, or precipitation, occurs most rapidly and in largest amount when the toxin and antitoxin are present in optimal proportions, and assay of the flocculation, or Lf, dose is readily carried out. In the standardization of commerical antitoxin, the flocculation titration is usually carried out to facilitate the subsequent guinea pig assay required by law.

The flocculation reaction is not sufficiently sensitive to measure the very small amounts of antitoxin demonstrable by the intradermal method, and there has been some interest in the use of passive hemagglutination as a sensitive *in vitro* method. Toxin, but apparently not toxoid, is adsorbed on tannic acid-treated red cells, and these are specifically agglutinated in the presence of antitoxin^{15, 45} to give results that are

closely similar to those obtained by the intradermal method (Chap. Two) at the 30 Lr level.

The Schick test. Immunity to diphtheria, then, may be measured by the amount of circulating antitoxin present in a given individual. A skin test has been devised by Schick, and is known as the Schick test, in which a minute amount of diphtheria toxin is injected intradermally. In the nonimmune the irritant action of the toxin gives rise to local erythema followed by necrosis and desquamation, and the reaction is said to be postive. In the immune, however, the toxin is neutralized by the antitoxin that is present, the characteristic reaction does not develop, and the reaction is negative. The amount of toxin injected is usually 1/50 of a guinea-pig MLD in a volume of 0.1 or 0.2 ml.; the Permanent Standards Committee of the League of Nations specifies 1/40 MLD in 0.2 ml. and 1/50 MLD in 0.1 ml. The dilute toxin is stable in 2 per cent peptone solution, a borate buffer-gelatin solution, and glycerol-gelatin solution, though not in phenol-saline.

For many years a negative Schick test has been regarded as indicating the presence of 1/20 unit or more of antitoxin per ml. in the blood serum and a positive test less than 1/40 unit. More recent experiments, however, have indicated that the so-called Schick level of immunity is much lower than this, in the neighborhood of 1/250 to 1/500 unit of antitoxin; negative reactions have been obtained in persons with as little as 0.0005 unit.

A scarification test in which diphtheria toxin is introduced by punctate scarification rather than intradermal injection has been introduced by Reh and is called *Reh's test*. It is said to be somewhat simpler to perform than the Schick test and, when carried out with a potent toxin (with a guinea-pig MLD of 2000 per ml.), to give parallel results with the Schick test.

The question of whether the Schick test is indicative of a degree of immunity such that subsequent infection is highly improbable is one that cannot be answered a priori. Experience has shown, however, that the assumption that a Schick-negative person is, for all practical purposes, immune, is pragmatically sound.

Prophylactic immunization.^{22,46} It was early observed that experimental animals can be immunized to diphtheria by the in-

jection of living cultures of the bacilli after a protective dose of antitoxic serum or by the inoculation of toxin neutralized with antitoxin.

Toxin-antitoxin. The mixture usually used contains 0.1 L₊ dose of toxin per ml. The toxin is slightly underneutralized (5 ml. of the mixture should produce diphtheritic paralysis in 300 gm. guinea pigs) but depends for its immunizing efficiency not on the slight excess of toxin but on a slow dissociation of the toxin-antitoxin complex to liberate free toxin. Administered in three doses of 1 ml. each at intervals of one to two weeks, toxin-antitoxin produces an immunity in 85 per cent of individuals inoculated. The immunity develops slowly, and one to six months may be required for the Schick reaction to become negative. Accidents may occur as a consequence of dissociation of the toxin-antitoxin mixture freezing in one instance produced such dissociation - but these are rare, particularly with the 0.1 L₊ dose mixture. There is the possibility of sensitization of the inoculated individual to horse serum.

Toxoid. The use of formol toxoid or anatoxin as an immunizing agent was introduced by Ramon in 1923 and has been widely adopted. As pointed out elsewhere (Chap. Nine), toxin treated with formaldehyde (in this case a potent toxin of more than 15 Lf doses per ml. is incubated with 0.3 to 0.4 per cent formalin at 37° C. for one month) loses its toxicity but retains its antigenicity and is a highly efficient immunizing agent. The administration of this material in three doses of 0.5, 1.0, and 1.0 ml. at intervals of two to three weeks renders 95 per cent of persons Schick-negative. It was at first thought that toxoid might entirely replace toxin-antitoxin as an immumizing agent, but this has not proved to be the case. Reactions to the bacillary protein, while not of great importance as a rule in young children, may be relatively severe in older persons, and its use is preferably restricted to children under 12 years of age. Reactivity may be tested for by the intradermal injection of toxoid—the Moloney

Toxoid-antitoxin floccules (the precipitate coming down at the optimal antigen-antibody ratio) have been used in England to a considerable extent. There is, presumably, a partial purification of the toxoid by precipitation with antibody. Another kind of

preparation that has been used in England is toxoid absorbed on aluminum phosphate, diphtheria phosphate toxoid or DPT. This material and toxin-antitoxin floccules have not been widely used in the United States. Toxoid precipitated with protamine appears to be an effective immunizing agent without giving the untoward reactions sometimes observed with alum-precipitated toxoid.

Alum-precipitated toxoid. It has been found that toxoid precipitated with potassium alum (small amounts, 1 to 2 per cent, are required) is superior as an immunizing agent to ordinary formol toxoid. Present preparations are treated with charcoal prior to alum precipitation to remove color and extraneous nitrogenous material. The precipitate is insoluble (it may be redissolved in sodium citrate or sodium tartrate) and remains in the subcutaneous tissue for a considerable time, to provide a prolonged antigenic stimulus. In spite of this, a single inoculation is not sufficient—as little as 11 per cent Schick conversion has been observed, together with a tendency to reversion—but two inoculations are as effective as three of fluid toxoid. Alum toxoid has the same tendencies to produce untoward reactions in older persons that are observed with formol toxoid.

Passive immunity. Susceptible, i.e., Schick-positive, individuals may be passively immunized to diphtheria by the injection of antitoxic horse serum or purified preparations of antitoxin. Such immunity is of relatively short duration and is not effective for longer than two or three weeks at the most.

The therapeutic use of antitoxin. Serum therapy is more successful in diphtheria than in any other disease, and there is no question of its efficacy in reducing case fatality rates. As in the case of tetanus and botulism, the therapeutic administration of antitoxin cannot bring about repair of tissues already damaged by toxin. Early administration is, therefore, essential, and there is progressive increase in the case fatality rate with each day's delay. There is no limit, beyond the volume, to the number of units that may be safely injected. Antitoxin is generally administered intramuscularly but in severe cases may be given intravenously. It is completely ineffective when given by mouth.

Usually horse serum contains 500 to 700 units per ml. and exceptionally 1000 to 1500. Concentration of the antitoxin by salting out and other procedures is generally practiced,

for, although some antitoxin is lost in the process, the concentration is increased with a corresponding reduction in the volume to be injected.

Epidemiology.⁴² The epidemiology diphtheria is considerably better understood than that of any other disease, in part because the causative agent can be isolated with relative facility from infected individuals, and in part because the Schick test allows the differentiation of the immunes and the nonimmunes. As in the case of other respiratory diseases, infectious material leaves the body in the secretions of the nose and throat, is transmitted from man to man by contact or infective droplets, and enters the body via the mouth and nose. Furthermore, the diphtheria bacillus is disseminated not only by persons with the disease but also through the agency of healthy carriers in whom there is no clinical evidence of infection. Unlike many of the diseases of the respiratory tract diphtheria is an immunizing disease, and prolonged or repeated contact with the bacillus results in the development of a solid immunity to the disease in its clinical manifestations.

Immunity and susceptibility. Schick testing indicates that while susceptibility is low in the first six months of life, owing to passive immunization with maternal antibody, the proportion of Schick-positives increases rapidly and is at a maximum in children under four or five years of age, then gradually declines in an unimmunized population. When immunization of children is widely practiced the prevalence of effective levels of antitoxin declines at about age 15 in some population groups, but not in others, presumably as a consequence of a greater carrier rate in the latter.¹³

Carriers. As indicated above, healthy individuals may harbor virulent diphtheria bacilli in their throats. These carriers need be neither immunes nor convalescents and are, for the most part, casual carriers. There is no precise information concerning the duration of this transient carrier state; it may possibly be about two weeks.

The proportion of carriers has been investigated by a number of workers. In a study of Baltimore schoolchildren, Doull and Fales found an average carrier rate of 2.32 per cent from November to May. On the basis of this Frost has estimated the carrier incidence in the five to 14 age group in that city to be 2538 per 10,000. At this

rate 75 per cent of the population becomes infected at least once in five years, 95 per cent in 10 years, and over 99 per cent in 15 years, while very considerable proportions would suffer repeated infections, the average being 2.5 infections per person in 10 years. Others have recorded considerably higher carrier rates; Dudley has reported 6.6 per cent in a boys' school, and repeated swabbings showed that at least 40 per cent carried the diphtheria bacillus at one time or another during the yearly period.

There is, it appears, ample opportunity for contact with virulent diphtheria bacilli, and there is every reason to suppose that the increasing proportion of Schick-negatives in the progressively higher age groups is a consequence of an active immune response to the presence of these microorganisms in the

nose and throat.

The control of diphtheria. It will be obvious from the above considerations that diphtheria is widely disseminated in the human population and cannot be controlled by the isolation of carriers or, except in a strictly limited sense, by quarantine of cases. The diphtheria bacillus is especially sensitive to erythromycin, which has been used with some success in treating carriers. 6, 50

The control of diphtheria is a matter of immunization and, if a sufficiently large proportion of the susceptible population is rendered immune, the prevalence of clinical diphtheria should decrease. Godfrey found that the immunization of 50 per cent or more of the children of school age, five to 14 years of age, did not produce a fall in the incidence of diphtheria in a number of large American cities, but that when 30 per cent or over of the preschool children were immunized there was a definite reduction in the incidence of diphtheria not only among these children but in the community as a whole. It is commonly assumed that immunization of 70 per cent of children suffices to control epidemic diphtheria. Other as yet unknown factors are involved also, for the disease persists in relatively high incidence in some well-immunized communities or groups. 30, 33

To what extent prophylactic inoculation and the therapeutic use of antitoxin have influenced the decline in diphtheria is problematical. It is believed by some that the present decline is in part a continuation of a periodic trend, accelerating in the past two decades.^{34, 47}

The disease was endemic during the first

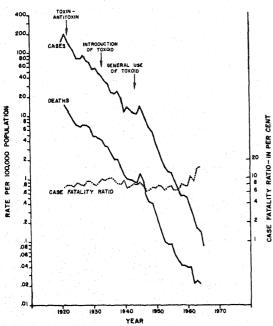

Figure 176. The decreasing prevalence of diphtheria in the United States during the period 1920–1965 as indicated by the morbidity and mortality rates. Note the lack of effect of the introduction of toxoid on the general trend, and the transitory rise during World War II. (Morbidity and Mortality Weekly Report, Annual Supplement, Vol. 14, No. 53. Communicable Disease Center, Public Health Service, U. S. Department of Health, Education, and Welfare.)

half of the nineteenth century though showing increasing epidemic tendencies. Between 1850 and 1860 a great pandemic developed, apparently from a focus in France, which swept over the world. A high mortality was maintained for 25 to 30 years, then around 1885 a decline set in which continued to about 1941. Immunization was not generally practiced until about 1920, though antitoxin therapy began somewhat earlier.

Beginning in 1941 there was a general increase all over the world in the prevalence of diphtheria. It apparently began in Germany in 1939, possibly due in part to mass movement of children into camps without adequate immunization, with a doubling of the already high (285 and 207 in Austria and Germany) morbidity rate, and an increase in severity as indicated by the increase in case fatality rates of 3.8 per cent in 1937–38, to 4.4 per cent in 1939, and 5.0 per cent in 1940. The disease spread into neighboring countries in northwest Europe. In Belgium the number of cases rose from 2419 in 1939 to 16,072 in 1943; in Holland

there were 1273 cases in 1939, 5501 in 1941, 19,527 in 1942, and 56,603 in 1943; in Norway there were 54 cases in 1939 and 22,787 in 1943. Diphtheria was the leading epidemic disease of the war years in Europe and an important cause of death in the German army. The rates have subsided from these highs, but diphtheria continues to be more prevalent in Europe than elsewhere in the world.⁴¹

These rates were reflected in U.S. military personnel stationed in Europe; diphtheria was a major problem with an incidence six times greater than for comparable troops stationed in the United States. Since 1946 the rate has declined. The number of cases and deaths in 1945 exceeded those of the previous five years, but the case fatality rate was not appreciably altered.³¹ In the United States there was a slight rise in the incidence of diphtheria, but it has subsequently declined; in 1966, 204 cases were reported in contrast to 17,987 in 1941. The decline has been in infants and children for the most part, but since 1940 there has been a slow but steady increase in the age groups over age 10,48 possibly a reflection of failure to re-immunize in the higher age groups. The residual infection tends to be concentrated in the nonwhite segment of the population. and further reduction would appear to be, in part, a matter of immunization of this group.35

THE DIPHTHEROID BACILLI

Microorganisms morphologically closely similar to and frequently indistinguishable from the diphtheria bacillus, known as diphtheroid bacilli, are found in man and lower animals. Three species are commonly observed in man. A form occurring in the human throat and readily confused with the diphtheria bacillus on microscopic examination was first observed by Löffler and by von Hofmann-Wellenhof. It is known as Hofmann's bacillus, Corynebacterium hofmannii, or C. pseudodiphtheriticum. It differs slightly from the diphtheria bacillus in that it is somewhat shorter and plumper and does not ferment dextrose. Most important, it does not form a soluble toxin and is readily differentiable from C. diphtheriae by the virulence test. It seems to be completely nonpathogenic for man and experimental animals.

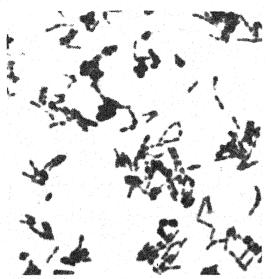

Figure 177. Corynebacterium pseudodiphtheriticum. Smear from pure culture stained with alkaline methylene blue. Note the irregular staining, club-shaped forms, and general close resemblance to C. diphtheriae. × 2000.

A second species, C. xerose, has been isolated repeatedly from a form of conjunctivitis known as xerosis, but its etiological relation to the disease is uncertain. It is also found on the skin, where it is presumably a part of the normal bacterial flora, and it is probable that its presence in xerosis is that of a contaminant. It does not form a soluble toxin. C. acnes has been found in acne pustules, but whether the association is causal is open to question. This organism stands somewhat apart from the other bacilli of the group in that it is micro-aerophilic and grows profusely under anaerobic conditions with the formation of a pink pigment. It also does not form a soluble toxin.

Animal pathogens. A number of species of corynebacteria are pathogenic for lower animals and rarely may infect man. C. pyogenes is one of the commonest causes of purulent infections in cattle, sheep, pigs, and goats; it is the cause of a form of mastitis, a few cases of abortion, arthritis, and granulomatous lesions in bovines, and is associated with calf pneumonia as well. Infections of man have been reported.3 It forms a soluble toxin, immunologically distinct from and considerably weaker than that of the diphtheria bacillus, which is hemolytic for rabbit erythrocytes and lethal for mice, and produces dermal necrosis in the rabbit similar to that produced by diphtheria bacillus toxin. This bacterium and its toxin have been studied extensively by Lovell.

C. ovis (C. pseudotuberculosis) or the Preisz-Nocard bacillus is also a pathogen of domestic animals. It produces a caseous lymphadenitis and ulcerative lymphangitis in sheep and horses referred to as pseudotuberculosis, and ulcerative lesions in other domestic animals. Like C. pyogenes, it forms a weak exotoxin distinct from diphtheria toxin. C. renale is closely related serologically to C. ovis and produces purulent infections of the urinary tract in cattle, sheep, horses, and dogs. C. equi is the cause of spontaneous pneumonia in foals and other infections in horses; this species is of interest in that it is variable in its reaction to the acid-fast stain, the coccoid forms retaining the stain while the bacillary forms take the counterstain, suggesting a relationship to the mycobacteria and acid-fast actinomycetes. C. enzymicum has been isolated from man primarily, but has been found as the cause of an epidemic ophthalmia of sheep. C. murisepticum is the cause of mouse septicemia and is apparently pathogenic for no other animals. The occurrence of these and other diphtheroid bacilli in diseases of domestic animals makes this group of microorganisms of considerable interest in veterinary medicine.

In addition to these a dozen or more authenticated species of corynebacteria are soil saprophytes or pathogenic for plants, producing diseases of wheat, alfalfa, ring rot of potato, bacterial canker of tomato and poinsettia, bean wilt, and the like.

Chapter Thirty-one

MYCOBACTERIUM

This genus includes a number of species of related bacteria which are most conveniently considered in three groups. The first includes the mammalian tubercle bacilli Mycobaterium tuberculosis var. hominis and Myco. tuberculosis var. bovis, and the avian tubercle bacillus, Myco. avium, together with the so-called "anonymous" or "atypical" mycobacteria. In the second group there are Hansen's bacillus or Myco. leprae and the rat leprosy bacillus, Myco. leprae murium. The third group is made up of Johne's bacillus, or Myco. paratuberculosis, and certain acid-fast bacilli isolated from cold-blooded animals, together with the saprophytic acid-fast forms. 11

THE TUBERCLE BACILLI

Tuberculosis is an old disease of man and is still one of the most widespread; it is estimated that over a million persons in the United States have active tuberculosis, and about half of these are known to the health departments. Its infectious nature was suspected by Fracastorius in the early part of the sixteenth century, and Villemin showed, in 1865, that the disease could be transmitted by the inoculation of tuberculous material. It was in 1882 that Koch demonstrated the tubercle bacillus by special staining methods, isolated and grew it in pure culture, and reproduced the disease by the inoculation of the bacilli.

Morphology and staining.36 The tubercle bacilli are slender, sometimes slightly curved, rods 2 to 4 μ in length and 0.3 to 1.5 μ in breadth. They occur singly but are often found in small groups, sometimes in compact masses in which the individual bacilli cannot be distinguished. The bacilli of the human

variety tend to be somewhat longer and more slender than those of the bovine type, but the morphology of both is variable, and no distinction can be made on this basis. The bacillary form is generally retained in the tissues; in culture longer filamentous forms are sometimes seen together with swollen or club-shaped cells resembling the diphtheria bacillus. Branched forms are present in cultures of the avian tubercle bacillus but are rarely seen in cultures of the mammalian bacilli. The occurrence of filamentous forms and true branching indicates the close relation of these bacilli to the higher fungi.

The tubercle bacillus is nonmotile and nonspore-forming and produces a capsular substance in artificial cultures, particularly when grown upon serum mediums. The granular structure of the individual cells is marked. Vacuoles often occur in abundance and may even give the stained cell the appearance of a chain of cocci. The significance of the small, deeply staining bodies sometimes observed within the cells is not clear; they do not show the enhanced resistance

characteristic of spores.

The tubercle bacilli cannot be stained by the usual staining methods that are effective with other bacteria, for there is a marked resistance to the penetration of dyes into the cell that is associated with the presence of relatively large amounts of unsaponifiable wax. The cells may be stained in two or three minutes by steaming carbol-fuchsin or by 18 hours' exposure to the dye at room temperature. Once stained, the bacilli are difficult to decolorize and resist the action of alcohol and dilute solutions of mineral acids and for that reason are termed "acid-fast." Retention of the fuchsin is considered to be, in part, a matter of permeability. 62 They may be demonstrated in smears by the Ziehl-Neelsen method, in which the smear is stained with hot carbol-fuchsin, declorized with acid alcohol, and counterstained with a dye of contrasting color. Methylene blue is most commonly used but some workers prefer other stains such as picric acid and Bismarck brown. Other stains, Sudan black B and neutral red, have been used for experimental purposes. It has been reported that bacilli from the lungs of infected mice are stained only by the former, and those grown in culture only the latter.117 The bacilli may also be stained with carbol-auramine, a dve that fluoresces a brilliant yellow in weak ultraviolet light. This method is seldom used, and then only for screening purposes. Nonacid-fast bacilli may be observed in young cultures.

Nonacid-fast but gram-positive granules, known as Much granules, were described by Much in 1907 as occurring in the material from cold abscesses and elsewhere in which acid-fast bacilli could not be demonstrated but which, nevertheless, proved to be infective. Considerable numbers of acid-fast bacilli, perhaps 100,000 per ml., must be present, however, before there is a reasonable chance of finding them in smears. Much maintained that these granules are viable and virulent and give rise to typical acid-fast rods. They have been observed by others, but their significance is open to question. Some regard them as degeneration products or artifacts of the staining procedure.

In broth cultures there is a thick, wrinkled

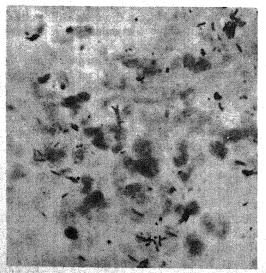

Figure 178. Mycobacterium tuberculosis. Acid-fast stained smear to tuberculous sputum. × 1050.

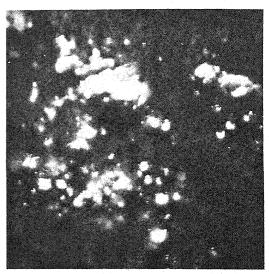

Figure 179. Colonies of the human variety of the tubercle bacillus, H-37 strain, on Löenstein's medium, at five weeks' incubation. \times 5.

skin of surface growth which tends to spread up the sides of the flask; masses of bacilli may become detached and sink to the bottom as a lumpy sediment. Growth on the surface of solid mediums is generally dry and granular with nodular, heaped-up areas. The human variety of the tubercle bacillus usually produces a pale yellow or orangeyellow growth on serum-containing mediums and a creamy or white growth in the absence of serum. The bovine variety is not pigmented on serum mediums. Some avian strains give a faint pink-colored growth on egg mediums. A peculiar almond-like odor is often noticeable in cultures of these bacteria.

Physiology. The tubercle bacillus is an aerobe and will not grow under completely anaerobic conditions. The mammalian varieties grow best at 37° C. and not at all below 30° C. or above 42° C.; the optimum temperature for the avian type, however, is 40° C. Growth is relatively slow, and four to six weeks are generally required for an abundant growth, although minute colonies appear in eight to 10 days. Most strains of the avian type adapt themselves readily to culture on artificial mediums and in time are able to grow much more rapidly, but others remain slow-growing.

Enriched mediums are required for primary isolation, and these usually contain eggs, glycerol, and sometimes dyes to inhibit the growth of contaminants. The commonly

used mediums are the Jensen modifications of Löwenstein's medium, containing egg, potato meal, bone marrow infusion, citrate, glycerol and asparagin, and malachite green; the egg yolk-potato medium of the American Trudeau Society; and McNabb's or Frobisher's modification of Petragnani's medium. Glycerolated potato is used by the French workers. Corper's medium is glycerolated potato with the modification that the pieces of potato are soaked for a short time in a solution of crystal violet before sterilization with the glycerol solution.

The human variety of the tubercle bacillus grows more abundantly on these mediums than does the bovine variety, and for that reason it is termed "eugonic" and the bovine type "dysgonic." These two varieties also differ in that glycerol is markedly favorable to the growth of the human type but does not so affect the bovine type. It is not known why glycerol exerts this favorable effect; attempts to substitute related compounds such as isopropyl alcohol, propyl alcohol, glycol, trimethylene glycol, and inositol have not been successful. Glucose, however, acts in much the same manner as glycerol. The metabolism of a variety of carbon compounds, including those functional in the Krebs cycle, has been studied in detail by Youmans and Youmans. 162 Egg yolk has been reported to contain a lipid growth factor, but this appears to stimulate rather than be essential to growth. Thiamin, pyridoxin, and riboflavin do not stimulate growth.

Growth occurs much more readily and upon simpler mediums after primary isolation. The human tubercle bacillus grows well upon nutrient agar or broth containing glycerol (2 to 5 per cent) and has been cultivated in a variety of synthetic solutions. One of the best known of these is Long's synthetic medium, which contains glycerol, asparagin, citrate, and inorganic salts. Dubos and his co-workers42 have found that growth is facilitated and occurs diffusely throughout the liquid medium in the presence of certain water-soluble lipids. A medium containing asparagin, glucose, phosphate, citrate, bovine serum albumin, magnesium sulfate, and a lipid commercially designated Tween 80 (a polyoxyethylene derivative of sorbitan mono-oleate), though it has appreciable growth-inhibiting activity, will give visible growth of the human variety of tubercle bacillus within two weeks. The medium becomes inhibitory in time, owing to the activity of lipase-contaminated bovine albumin preparations, which liberates oleic acid to bacteriostatic concentrations from the Tween 80; the effect can be eliminated by the use of commercial crystalline bovine serum albumin, by the addition of 0.01 per cent sodium fluoride, and by other means. The bovine type grows poorly or not at all on these mediums and is benefited only slightly by the presence of glycerol. The avian type of tubercle bacillus, however, grows better than the human type after a few transfers, and good growth may be obtained on nutrient agar in the absence of glycerol. Like the human type the avian bacillus grows much more profusely in the presence of glycerol. These cultural differences in the three types of tubercle bacilli are of little significance in their early differentiation, for several transfers over a period of months are necessary before they are obvious.

The biochemical reactions of the tubercle bacilli have not been studied at length. Growth occurs in milk, but no visible change is produced. Indol is said not to be formed. In glycerol broth, cultures of the bovine type become alkaline, while those of the human type become slightly acid. The conventional fermentation test is not readily applicable to the tubercle bacilli because of their very slow growth. The necessary prolonged incubation tends to give inconsistent results, possibly because of further decomposition of organic acids, concurrent deamination, etc. The use of very heavy, nongrowing suspensions of the bacilli in carbohydrate-containing mediums has indicated the possibility of useful differentiation. It is reported¹⁴⁰ that strains pathogenic for man but not for chickens ferment trehalose but not xylose, while strains pathogenic for chickens but not for man ferment xylose but not trehalose. The reduction of nitrate and the decomposition of nitrite have also been suggested as differential characters. 156

Growth in cell culture. The growth of tubercle and related bacilli in animal tissue cells in culture has been of interest since the early studies of Maximov on the pathogenesis of such infections. More recently cultures of spleen and liver explants, monocytes, and cells of the HeLa line have been used as substrates with particular reference to the differentiation of strains with respect to virulence. Infection of the host cells in maintenance mediums occurs within the first day or so, and proceeds rapidly in

growth mediums. It has been observed consistently that virulent strains grow more rapidly, with appreciable growth in three to five days, and there is concurrent destruction of the host cells. The tissue culture method appears to be less sensitive than conventional culture for primary isolation.

Chemical composition. The chemical composition of the tubercle bacilli has been more intensively investigated than that of any other bacteria. These bacilli are of particular interest in this connection because of their high content of lipoidal substances, which may make up as much as 40 per cent of the dry weight. Protein, a considerable proportion of which is nucleoprotein, makes up about half the dry weight, and polysaccharides are found in relatively small amounts. 119

The lipids have been studied at length by Anderson¹ and his co-workers. In addition to neutral fat, two general types of material may be distinguished:

(1) Phospholipid, containing saturated and unsaturated fatty acids including the well known palmitic, linoleic, and linolenic acids, together with two acids peculiar to the tubercle bacillus, *phthoic acid*, isomeric with cerotic acid, and *tuberculostearic acid*, isomeric with stearic acid and optically inactive.

(2) An acid-fast wax, containing polysaccharides hydrolyzing to mannose, arabinose, and galactose; a soft wax which is a complex glyceride; and an unsaponifiable wax (acid-fast) made up of higher alcohols and including a high molecular weight saturated hydroxy-methoxy acid termed mycolic acid; a higher alcohol designated phthiocerol; and a levorotatory fatty acid, mycocerosic acid. Acid-fastness is associated with the presence of mycolic acid.

Some of these substances appear to be physiologically active. The unsaponifiable acid-fast wax apparently stimulates the multiplication of undifferentiated connective tissue cells, and phthoic acid induces a proliferation of epithelioid cells. 113 A toxic lipid fraction, extractable in monochlorbenzene. is thought to contribute to the primary toxicity of massive inoculums, but is of uncertain significance in the disease. 135 A yellow pigment is found in the neutral fat which is designated phthiocol and is a hydroxynaphthaguinone which may be reversibly reduced at a relatively low potential. This substance is identical with vitamin K except for the substitution of a hydroxyl group for the phytyl radical on the third carbon.

Polysaccharide mixtures, containing immunologically active and inactive substances, have been isolated from mammalian tubercle bacilli, but their significance is not as yet understood. The protein constituents of the cell appear to be the most important immunologically and have been studied in connection with the preparation and activity of the various tuberculins.

Cord factor.¹² The tendency of tubercle bacilli to grow in filaments, or cords, in liquid culture was found by Middlebrook, Dubos, and Pierce in 1947 to be associated with the virulence of human and bovine varieties of the microorganism. On treatment with petroleum ether, the filaments break up, and a lipid substance is extracted which is acid-fast and toxic to leucocytes and mice. This substance was designated the cord factor by Bloch. Its association with virulence is not altogether clear, for it may be extracted from the attenuated BCG strain (see below) and from nonpathogenic forms such as the smegma bacillus.

Resistance. Although having much the same degree of resistance to heat as the vegetative cells of other bacteria, the tubercle bacilli are relatively highly resistant to drying, chemical disinfectants, and other deleterious environmental influences, very likely as a consequence of their contents of wax. In putrefying sputum the bacilli may remain viable for weeks or months and in dried sputum kept in a cool dark place for as long as six to eight months. Sputum that is completely dried, so that particles are capable of floating as dust in the air, may be infective for eight to 10 days. In dried sputum they may survive 100° C. for an hour but are killed in the usual way by moist heat. Phenol penetrates the bacilli only slowly, and a 5 per cent solution requires 24 hours to kill the bacilli in sputum. The action of other disinfectants is similarly retarded, and hypochlorites and certain synthetic detergents have almost no effect on these bacteria. Tubercle bacilli are readily killed by exposure to direct sunlight; bacilli from cultures are killed within two hours but in sputum may survive 20 to 30 hours of such direct exposure.

A number of different kinds of substances are bacteriostatic for the tubercle bacilli, including streptomycin, ρ -aminosalicylic

acid (PAS), sulfones, thiosemicarbazones, and certain pyrimidine derivatives such as isoniazid. These substances are extremely useful for chemotherapeutic purposes (see below).

Variation. The variability of the tubercle bacilli has been studied extensively, but with inconclusive results. Colonial variants. thought by some to be analogous to the S and R variants of other bacteria, have been observed, and it has been claimed by some workers that the S type is the more virulent. and by others that virulence and colonial morphology are independent. The colonial morphology of the tubercle bacilli is, to a considerable degree, a transient adaptation to environmental conditions, and prompt alteration of colonial appearance results on transfer to a different medium. For example, it has been observed that colonies growing in the presence of ether extract of egg volk are smooth and markedly different from the usual colonial type, but the effect is only a temporary physical one. The status of the S-R variation in the tubercle bacilli is, then, by no means clear as vet.48

Bacille Calmette-Guérin. A bovine strain of the tubercle bacillus was rendered completely avirulent by Calmette, who cultivated it over a long period (230 transfers in 13 years) on bile-glycerol-potato medium. This strain is designated as BCG (Bacille Calmette-Guérin) and has been of particular interest in connection with active immunization against tuberculosis. The nature of the change which resulted in the loss of virulence is completely unknown. The loss appears to be permanent and virulence does not reappear on transfer to ordinary mediums.

Life cycles. The pleomorphic tendencies of the tubercle bacilli, coupled with the occurrence of nonacid-fast rods in young cultures and the granular elements described by Much, have been interpreted by a number of workers as indicative of a cyclic succession of morphological types, or life cycle, through which these bacilli go. As pointed out elsewhere (Chap. Seven), evidence suggesting the occurrence of life cycles of bacteria is subject to various interpretations.

Filterable forms. L variation⁷⁸ occurs during which viable granules, perhaps to be regarded as Much granules, are produced. The viable fragments, including filaments as well as granules, revert to the bacillary

form on culture on the conventional mediums. The latter probably account for the many reports of filterable forms, or "ultravirus" of tubercle bacilli.

Drug resistance. Like other bacteria, the tubercle bacilli may become resistant to chemotherapeutic drugs in vitro and in vivo.2, 22, 99, 121 The latter is more common with these bacteria than with other kinds because of the nature of the disease and the prolonged treatment required, and because resistance to certain of the effective drugs, streptomycin and isoniazid in particular, is especially prone to occur. Isoniazid resistance is accompanied by a loss of catalase activity by tubercle bacilli, but some catalase activity persists in resistant saprophytic mycobacteria. There is evidence that the latter contain two catalase systems, one of which is not isoniazid-sensitive.145

The practical importance of drug resistance depends upon the drug and its toxicity. For example, a blood level of 10 to 15 μ g. per ml. of streptomycin may be attained, and sensitive strains are inhibited in vitro by 0.5 μg. per ml., slightly resistant strains by 2 to 4 µg. per ml., moderately resistant by 200 to 400 μ g, per ml.; and more than 50,000 μ g. per ml. is required to inhibit the growth of highly resistant strains. Blood levels of isoniazid of 3 μ g. per ml. may be attained, and sensitive strains are inhibited by 0.025 μg. per ml. in vitro. Thus a proportionately higher resistance must occur in the case of isoniazid than of streptomycin to allow growth in therapeutic concentrations. The assay of drug sensitivity is complicated by the slow growth of the bacilli17, 139 and more rapid methods have been devised based on the use of suspensions of bacilli and indicators of oxidative metabolism such as resazurin or tetrazolium. 69, 75, 148

The facility with which resistance to a single chemotherapeutic agent develops is such that for practical purposes it is necessary to reduce the development of drug resistance by the use of combinations of drugs. As described elsewhere (Chap. Seven), if the resistant strain arises as a consequence of the selection of a chance mutant by the drug-containing environment, and resistance to one drug is independent of that to another, the probability of occurrence of a double mutant is given by the product of the two mutation rates and becomes extremely small. The development of drug resistance in vivo

is, in fact, markedly inhibited by the use of two drugs in combination, commonly streptomycin plus PAS, isoniazid plus PAS, etc. Resistant strains do not appear to differ significantly from the sensitive parent strain except in the case of those resistant to isoniazid, which are appreciably less virulent though still capable of producing fatal disease in man. 138, 144

Pathogenicity for man. Tuberculosis is still the most important specific communicable disease in the world, affecting more than 50,000,000 people. In the United States 50,000 new cases are reported each year, and there are about 10,000 deaths annually. It is estimated that of 30,000,000 people currently infected but without evidence of active infection, some 2,000,000 will eventually develop tuberculosis.

The mammalian tubercle bacilli, both bovine and human varieties, are pathogenic for man. The human type is practically always responsible for pulmonary tuberculosis in adults and is usually found in children also. The bovine variety may occur occasionally in pulmonary tuberculosis in children but is more often found in infections of other tissues. Mixed infections with the two types of tubercle bacilli have been reported but are rare.

The avian tubercle bacillus is generally considered to be, for all practical purposes, nonpathogenic for man. Cases of human infection, however, are reported from time to time, ^{23, 43, 76} and some studies have suggested that it may be more important in human disease than generally believed. In one study carried out in Germany, 8.5 per cent of 218 positive specimens were avian tubercle bacilli. ⁹¹ It resembles certain of the anonymous mycobacteria (see below), with which it may be confused.

Routes of infection. The tubercle bacillus may enter the body by way of the genitourinary tract, the conjunctiva, the skin, the alimentary tract, and the respiratory tract. Primary infection of the genitourinary tract is possible but, under natural conditions, rarely occurs. Infection through the conjunctiva takes place readily under experimental conditions; its frequency under natural conditions is not known, for the cervical lymph glands, where the infection would first appear, are readily infected by other channels. Infection through the skin is relatively rare; whether the bacilli can penetrate the intact skin is uncertain, but

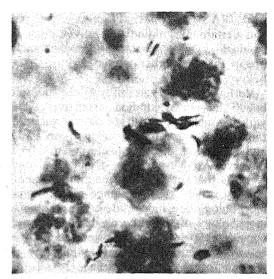

Figure 180. Tubercle bacillus. Acid-fast stained smear of pus from a liver abscess in a rhesus monkey. × 2600.

they may enter through abrasions or other traumatic injuries. Primary infection of the skin generally results in verruca tuberculosa (pathologist's wart) or lupus vulgaris.

Primary infection by the alimentary tract is a consequence of the ingestion of tubercle bacilli in infected food, most commonly milk, and occurs with considerable frequency in children. Secondary infection may occur, especially in children, by swallowing tuberculous material of respiratory origin. In the upper portion of the alimentary tract the bacilli enter the body tissues through the faucial, pharyngeal, and lingual lymphoid follicles and first affect the upper cervical and retropharyngeal lymph glands. Tuberculous lesions of the tonsils are not uncommon though rarely conspicuous. The stomach is rarely a portal of entry, but the bacilli penetrate the intestinal mucosa by way of Peyer's patches.

The respiratory tract is the most frequent and most important route of infection with the tubercle bacillus, and the facility with which this occurs is demonstrable under both controlled and natural¹¹¹ conditions. The coarser infectious particles in inspired air are filtered out and deposited on the nasal, buccal, and pharyngeal surfaces, and the bacilli, upon penetration, set up focal infections in the local lymphatic tissue. Fine droplets or particles of dust, however, may, and frequently do, enter the lungs directly (Chap. Ten).

The spread of infection in the body. bercle bacilli are disseminated through the body from primary or secondary foci of infection by way of the lymph or the blood stream, or directly by extension along contiguous surfaces. Distribution via the lymphatics occurs more readily in children than in adults, and the bacilli may localize at almost any point but most commonly in the lymph nodes. Bacilli present in the thoracic duct may gain entrance to the blood stream. The blood stream may also be invaded directly through erosion of a vessel wall by a focus of infection. The bacilli are transported throughout the body by the blood and give rise to acute miliary or chronic disseminated tuberculosis. An example of the pathogenesis of hematogenous spread occurred following an instance of intravenous self-inoculation with suicidal intent:59 general miliary infiltration throughout both lungs occurred between the sixteenth and twenty-first days, but the tuberculin reaction did not become positive until the twentysixth day.

Spread by extension occurs most frequently in ulcerative pulmonary tuberculosis with the breaking down of foci of infection and the consequent presence of bacilli in the sputum. The pleura and pericardium may be invaded directly from a focus of infection in the lungs. The infection of such serous surfaces may be localized and fibrinous and result in adhesions, or it may assume an acute miliary form. Direct extension may also occur elsewhere, as from the kidneys to the ureters and bladder or into the peritoneal cavity and adjacent areas from intestinal ulcers. Practically every organ and tissue of the body may be invaded by the tubercle bacillus.

Tuberculosis in man is most commonly the pulmonary form with a primary invasion of the apices, and over 90 per cent of the deaths from tuberculosis are due to the pulmonary type. Whether primary infection is a direct consequence of inhalation as believed by Koch, or whether it is in most cases of hematogenous origin following a preliminary infection of the lymphatic system as urged by Calmette, is not altogether clear, but on the whole the evidence favors inhalation infection. Although pulmonary tuberculosis is by far the most common form of infection in adults, it is somewhat less frequent in children, but precisely how much less is not known with certainty. Pulmonary infection in children differs from that in adults in that the hilum glands are involved. Involvement of the lymphatics is frequent in children. The anatomical distribution of the lesions usually takes one or the other of two well-defined forms; in the one the lesions are found predominantly in the tracheobronchial lymphatics and in the other in the mesenteric lymph nodes. In general, children show a tendency toward generalized infection.

Other tissues and organs are involved less frequently. The spleen, liver, and kidneys are sometimes infected. Tuberculosis of the adrenals gives rise to Addison's disease. Infection of the skin or lupus is not uncommon. Bone and joint tuberculosis is more common in children than in adults, and tuberculosis meningitis is not infrequent in the young. It will be clear that tuberculous infection may take a variety of clinical forms.

The tubercle. Lesions caused by the tubercle bacillus, in whatever part of the body they occur, usually possess a definite although not absolutely characteristic appearance and histological structure. Small nodules or tubercles, plainly visible to the naked eye, are so uniformly observed in advanced infections with the tubercle bacillus that their presence has given the name to the disease. The young tubercle probably originates from the fixed cells surrounding the invading bacilli. By the proliferation of the fixed cells, elongated "epithelioid" cells are developed in more or less definite concentric layers and come to form the substance of the tubercle. So-called giant cells or foreign-body giant cells soon appear in the developing tubercle; these are huge multinuclear masses of protoplasm thought by some to be especially distinctive of true tubercle formation, though it is doubtful if this criterion can be maintained. Either they are produced by the fusion of a number of macrophages or they are of single-cell origin. While the formation of epithelioid and giant cells is going on, leucocytes, at first polymorphonuclear leucocytes and later lymphocytes, cluster around the periphery of the tubercle. Degeneration of the tubercle eventually sets in, the central portion becomes necrotic, and this is followed by caseation and then by softening of the caseous mass.

In some cases calcium salts are deposited in the tubercle (calcification), converting it into a hard, dry, friable body which may become encapsulated and completely walled off from the surrounding tissues. In other instances, however, this healing process does not take place, and there is instead an extension with coalescence and the formation of confluent masses that may reach a diameter of 4 or 5 cm. The erosion of a blood vessel may occur, and the discharge of large numbers of the bacilli into the blood stream leads to a general diffusion of small tubercles of the size of millet seeds (acute miliary tuberculosis).

The early stages of tubercle formation, characterized by cell proliferation and leucocytic infiltration, are probably a response to a chemical or mechanical stimulus caused by the presence of the bacilli; the later changes, leading to necrosis and caseation, may be attributed to the action of the bacterial products. The host becomes sensitized to the bacillary substance, and the allergic response of the tissues is involved to no small extent.

Predisposing factors. Few diseases are as completely dominated by predisposing factors as tuberculosis. Infection with the tubercle bacillus is exceedingly common, and there are few adults, particularly those living in cities, who escape. The proportion of individuals coming to autopsy who show evidence of infection is very high and has been reported as high as 97 per cent. In one series of cases, for example, it was found that 25 per cent of 10-year-olds, 55 per cent of 20-year-olds, 80 per cent of 30-year-olds, and over 90 per cent of individuals over 50 years of age show calcified lesions of infection. The bacilli, then, are present in the great majority of adults and also in many children, but the development of clinical tuberculosis is restrained by the nonspecific resistance of the host. For example, in one study of tuberculin-positive children carried out prior to the advent of chemotherapy, 91 per cent showed no clinical illness though radiologic signs were present but eventually resolved, 5.4 per cent had clinical illness but recovered, and 3.6 per cent died.90

Predisposing factors, therefore, are those which tend to interfere with normal physiological well-being and include such things as insufficient or unsuitable food, prolonged exposure to dampness, a sedentary life, and chronic fatigue. In World War I the incidence of tuberculosis rose in this and other countries, and in World War II the same

tendency was again apparent in Europe. In both man and animals tuberculosis is a disease associated with confinement, of men in houses and cattle in stables. The opportunities for transmission of the infection are, of course, much greater in community life.

There is a marked occupational predisposition to tuberculosis in the dusty trades, and the constant inhalation of almost any kind of dust results in an increased incidence of pulmonary tuberculosis. Silica dusts, however, appear almost specifically to predispose to tuberculosis, and the incidence of infection in those constantly exposed to such dusts is much higher than that in the general population.

It has long been suspected that there are familial or hereditary tendencies to tuberculosis in man. Resistance to infection in experimental animals is to some degree genetically determined, but the conclusive demonstration of a similar phenomenon in man is difficult owing to both a long generation time and the inability to carry out appropriate breeding experiments. The incidence of new infection in tuberculous families is considerably greater than in the general population, but whether this is a consequence of increased risk alone or, in part, of genetically determined factors is not clear. In any case the disease itself is not inherited. and congenital tuberculosis occurs only rarely.57, 155

The relation of childhood infection to clinical tuberculosis in the adult has been a matter of considerable interest, and it has been suggested that pulmonary tuberculosis of the young adult may, in many instances, be a consequence of the lighting up of an old infection.²⁹ Tuberculosis in the adult may also be a consequence of reinfection rather than of a flaring up of the healed or partially healed lesions from childhood infection. A considerable period, possibly years in some instances, may elapse between reinfection and the appearance of tuberculosis in clinical form.

Bacteriological diagnosis.^{84, 102, 106} Tubercle bacilli are discharged from the infected individual in sputum and urine and may be demonstrated in these materials and in gastric washings, spinal fluid, or infected tissues, depending on the location of the infection. Of specimens from these sources, those obtained by gastric lavage are of particular value in respiratory tuber-

culosis in children, who tend to swallow sputum, and are also useful in adult infections. Results must be interpreted with caution because of the presence of saprophytic acid-fast bacilli in the gastrointestinal tract derived from the ingestion of foods, especially fruit, on which these forms occur; furthermore, there is some reason to believe that some fats and oils may impart acid-fast properties to ordinarily nonacid-fast bacteria present in the alimentary tract. The presence of the bacilli may be shown either directly or after concentration by examination of stained smears, 114 culture, and guinea pig inoculation.

As a rule, some method of concentration is desirable,³⁴ for not less than 100,000 bacilli per ml. must be present before there is a reasonable chance of finding them by microscopic examination. The resistance of the tubercle bacillus allows treatment of the specimen with hypochlorite or NaOH to destroy contaminants and digest the viscous sputum to facilitate concentration by centrifugation. The sediment is used to prepare smears for direct examination and to inoculate culture mediums and/or guinea pigs.

Smears are usually stained by the Ziehl-Neelsen method. The demonstration of acid-fast bacilli allows a provisional diagnosis but does not indicate whether the bacilli were viable or whether they are virulent tubercle bacilli. Their presence in urine specimens in particular must be interpreted with caution because of the frequent occurrence of the smegma bacillus, which is also acid-fast.

Guinea pigs are inoculated in the groin or in the muscle of the thigh. If a reasonable number of tubercle bacilli have been inoculated, enlargement of the regional lymphatics may be noted in two or three weeks, the pig becomes emaciated by four to six weeks and usually dies not long after. With very small numbers of bacilli evidence of the infection may be delayed two or three weeks longer. If it is not obviously ill or does not die, the animal should be kept for eight weeks before sacrificing. At autopsy the regional lymph nodes will be found to be enlarged and filled with caseous material. Necrotic areas in the spleen and liver are characteristic of the gross pathology in this animal; tubercles are seldom seen, and the lungs are only slightly affected and the kidneys almost never. Tubercle bacilli may be cultured from the lesions and found in acidfast-stained smears. Some workers tuberculin-test the animals before inoculation and three to four weeks afterward, the development of hypersensitivity indicating infection. If differentiation of the human and bovine varieties of the bacillus is desired, rabbits may be inoculated.

A variety of mediums, containing glycerol and egg, may be used for culture, the particular medium varying from one laboratory to another. The culture is commonly enclosed, as in a screw-cap culture tube or with paraffin poured over the cotton plug, to minimize drying, but a small hole needs to be left to allow air exchange. Characteristic colonies of tubercle bacilli appear after about three weeks' incubation. Extended incubation, to as long as five months, may give a few additional positive cultures. 103 Culture is not identification, of course, and acid-fast bacilli, which grow like the tubercle bacilli, are occasionally found in nontuberculous lesions.

Chemotherapy. 79, 80, 157 Effective otherapy of tuberculosis requires that the chemotherapeutic agent be diffusible into the tuberculous process as well as having specific antibacterial activity. In addition, the necessity for administration over relatively long periods accentuates the problems of toxicity and the development of drug resistance by the microorganism. Prior to 1938 no substances of practically significant activity were known, but while the ideal chemotherapeutic agent for this disease has not been found, a number of drugs of reasonable efficacy are now available. These fall into two groups, viz., the synthetic compounds and the antibiotics.

The synthetic tuberculostats. There are four groups of these: the sulfones, the aminohydroxybenzoic acids, the thiosemicarbazones, and the pyrimidine carboxylic acid derivatives. The observation that sulfanilamide affects the progress of experimental tuberculosis led to the preparation and trial of related compounds. Of these, the sulfones, 4.4'-diaminodiphenvl sulfone and its derivatives such as Promin, Diasone, and Sulphetrone, were found to be partially effective chemotherapeutic agents. All are toxic, the most common effect being on the erythrocytes, and, while toxicity may be reduced by adjusting dosage, it has not been possible to eliminate it, probably because the activity of derivatives is a consequence of their degradation in vivo to the parent compound.

The observation that benzoates and salicylates stimulate the respiration of the tubercle bacillus *in vitro* provided the basis for the discovery of the chemotherapeutic activity of *p*-aminosalicylic acid, the most active of the compounds tested. This substance is of low toxicity and is readily absorbed from the gastrointestinal tract. It has appreciable chemotherapeutic activity when given alone, but its greatest utility is in combination with streptomycin or isoniazid.

The thiosemicarbazones are more effective chemotherapeutic agents than the sulfones or salicylates and have been used relatively widely in Europe but not in this country. The compound p-acetaminobenzal-dehyde thiosemicarbazone (Tibione) has been tested extensively together with a number of derivatives. All of these are relatively toxic substances and give severe side reactions, including anemia and liver and kidney damage in addition to gastrointestinal disturbances.

A number of pyrimidine derivatives, isonicotinic acid hydrazide (isoniazid) and related compounds such as the isopropyl derivatives, are available under a number of proprietary names and are widely used and effective chemotherapeutic agents although they have some neurotoxicity.

Antibiotics.⁴⁷ Streptomycin was the first of the antibiotics to be used for the therapy of tuberculosis, and continues to be the most widely employed. Most other antibiotics effective in the treatment of acute infectious diseases are not satisfactory, but the broad-spectrum antibiotic cycloserine (D-4-amino-3-isoazolidine) has been used to a considerable extent as an effective chemotherapeutic agent.

As noted earlier, the various chemotherapeutic agents are commonly used in combination in the treatment of tuberculosis to minimize the occurrence of drug-resistant variants.^{27, 74} While commonly given separately, very many compounds or complexes of two drugs have been prepared under a variety of names, and are described elsewhere (Chap. Six).

Antibacterial activity in vivo. Assay of the chemotherapeutic efficiency of tuberculostatic drugs is dependent upon the nature and stage of the infection. For example, in early infection, growth of the bacilli is largely intracellular, and streptomycin and PAS do not penetrate macrophages, though isoniazid does, to affect the phagocystosed bacilli, but when the individual is allergic (see below), growth tends to be more frequently extracellular. Similarly, in tuberculous lesions the bacilli grow most densely at the periphery of the caseous zone, and as the lesion expands they are engulfed in caseous material and lie dormant. Such dormant bacilli are not appreciably affected by the bacteriostatic activity of drugs, and the concentraton of drug is lower in such material than in the blood. Thus a focus of infection may persist in the individual undergoing chemotherapy and result in relapse, and possibly infection with drug-resistant bacilli, when therapy is discontinued. The intracellular persistence of viable bacilli during chemotherapy may be of some small significance in pulmonary tuberculosis, but of very considerable importance in tuberculosis meningitis.

The anatomical changes occurring in the tuberculous lesion during chemotherapy have been summarized by Auerbach,3 who groups them as follows: (1) a rapid and extensive clearing of the perifocal reaction, (2) a greatly decreased width of fibrous capsules around necrotic foci, (3) decreased thickness of the cavity wall and overlying pleura, (4) a decrease in pulmonary fibrosis and emphysema, (5) a marked decrease in the occurrence of massive pulmonary hemorrhages, (6) a difference in the mode of cavity healing, and (7) an accelerated healing of the tuberculous process. The last is especially evident when treatment is begun early in the disease and appears as an accelerated development of collagen fibrils and a corresponding decrease of cells and capillaries of the granulation tissue around the necrotic foci and the walls of tuberculous cavities. The changes differ somewhat depending the chemotherapeutic upon agent.73

Immunity^{120, 151} The immune response of the animal body to the presence of the tubercle bacillus is indicated by the appearance of agglutinins, precipitins, opsonins, and complement-fixing antibodies in the serum. This response is not marked, however, for these antibodies are present only to low titers. Erythrocytes sensitized with tuberculin are passively agglutinated,⁸³ but this reaction appears to have only limited diagnostic or prognostic value.

The most striking immune response is the development of hypersensitivity of the delayed type to the bacillary cell substance. Within limits, this allergic response is protective against reinfection, as shown by Koch's early experiments. He showed that the subcutaneous inoculation of the normal guinea pig with tubercle bacilli produces no immediate response, but that in 10 to 14 days a nodule develops which breaks down to a persistent tuberculous ulcer, and the regional lymph glands become swollen and caseous. In the tuberculous animal, however, an indurated area appears within a day or two, and there is slight necrosis with the formation of a shallow ulcer which heals promptly without the development of gross tubercle tissue or the invasion of the adjacent lymphatics by the bacilli. This is known as the Koch phenomenon.

This resistance to reinfection is relative and is not shown unless the primary infection is of some weeks' standing or large numbers of bacilli are injected. Experimental studies with guinea pigs have shown that immunization increases the infective dose about 1000-fold.¹⁰ Animals may be sensitized not only by infection with virulent bacilli, but also by the inoculation of attenuated or killed bacilli. Sensitization with preparations of the bacillary cell substance is difficult and very large doses must be administered. Raffel¹⁰⁰ has shown that the reaction is a result of inoculation with tubercle bacillus protein combined with a purified wax fraction consisting of an ester of polysaccharide and higher alcohols with hydroxy fatty acids; the protein alone produces an immune response with formation of precipitins. A protein fraction separated by urea extraction has been found to sensitize animals,35 and an effective immunizing preparation of subcellular particulate material has been prepared from virulent human strains, and also from BCG but of much reduced immunizing efficiency, by Youmans and his co-workers. 163, 164, 169 Cell wall fractions alone have also been found to be immunogenic. 108, 109

The hypersensitivity so produced is of the delayed kind typical of infection allergies. It is not passively transferable by serum but may be transferred by cells from a hypersensitive animal.

Tuberculin. The sensitized animal will react to the soluble cell substance of the tubercle bacillus, preparations of which

have been called tuberculin. Tuberculin is usually prepared from the human type of tubercle bacillus, though bovine tuberculin is practically as active as human tuberculin in infections with the human bacillus; avian tuberculin, although considerably less active, will also produce a reaction. A variety of tuberculins have been prepared, of which only a few need be noted here. The first of these was made by Koch, and consisted of the filtrate of a glycerol-broth culture of the bacilli concentrated by evaporation on a water bath to about one-tenth its original volume (the activity is heat-stable). This material is "original" or "old" tuberculin (TO or OT). A "new" tuberculin (TR-tuberculin residuum) was prepared by Koch in 1897 by macerating living virulent bacilli, extracting the mass with water, and then making an emulsion of the residuum. He later advocated the use of an emulsion (BEbacillary emulsion or Bazillenemulsion) of the entire substance of young virulent bacilli in 20 per cent glycerol, actually a vaccine. Denys introduced the use of the unaltered filtrate from broth cultures (BF-broth filtrate). None of these later innovations, however, proved to be superior to old tuberculin, and the original preparation, or slight modifications of it, has been widely used.

The active principle of tuberculin is protein in nature, and the cultivation of the tubercle bacillus in glycerol-asparagincitrate synthetic solutions by Long and Seibert has made possible the study of the active principle in purified preparations. The activity is associated with a number of protein fractions, one of which Seibert prepared in crystalline form. A more satisfactory preparation of low molecular weight, ca. 2000, has been isolated by Seibert by precipitation with trichloracetic acid. Originally designated SOTT (synthetic medium old tuberculin trichloracetic acid precipitated), it is now known as PPD (purified protein derivative).118

The comparative merits of OT and PPD have been the subject of a series of investigations. OT is relatively unstable in dilutions, while PPD, a dry powder, is "dry-diluted" with lactose and is indefinitely stable in this form. Different lots of OT vary somewhat in their activity; the activity of PPD preparations is relatively constant. It appears that PPD is quite as satisfactory as OT in actual use and, because of its stability

and constant activity, is regarded by many as superior to OT.

The tuberculin reaction. 72 Three types of reaction may be elicited in the sensitized. i.e., infected, animal by the injection of tuberculin. In addition to a local inflammatory reaction at the site of inoculation, there is a focal reaction manifested as an acute congestion around tuberculous foci which, if marked, may aggravate the pathological process, and a constitutional reaction in which the temperature rises to a peak of 102° to 104° F. and subsides in 12 to 18 hours. In man the constitutional reaction also includes malaise, pain in the limbs, and, perhaps, vomiting, dyspnea, and other symptoms. These reactions do not appear in normal animals. The utility of tuberculin is, then, two-fold; it may be used for diagnostic purposes and it has therapeutic value, though the latter is strictly limited.

The diagnostic tuberculin test in man is generally a skin test. Koch's original method consisted of subcutaneous injection of tuberculin. The cutaneous reaction of von Pirquet involves the rubbing of tuberculin onto the scarified skin. In the Mantoux test, the one most commonly used today, graded doses of tuberculin are injected intradermally, usually starting with 0.01 mg. of OT and going as high as 1.0 mg. or even 10 mg. on rare occasions (0.1 ml. of a 1:100 dilution of OT is supposed to contain 1 mg.; the standardization of new batches is biological and carried out in guinea pigs infected with virulent tubercle bacilli). Smaller amounts of PPD are used, since it is in dry, pure form, usually 0.00005 to 0.005 mg. A "patch test" has been introduced by Vollmer in which squares (0.8 cm.) of thin filter paper, impregnated with tuberculin about four times as strong as the original old tuberculin and dried, are taped on the cleansed skin over the sternum or upper edge of the trapezius. The patch test appears to be somewhat less sensitive than the intracutaneous test of Mantoux. Since these are all skin tests, only the local inflammatory reaction is observed in infected persons. There is evidence, however, that repeated tuberculin testing may result in a local sensitivity in the uninfected per-SOn 41, 94

In young children a positive tuberculin reaction may be taken as indicative of infection. Reactivity may be temporarily depressed under some conditions, especially

in the incubation and early stages of measles, or by measles immunization. ¹³⁷ It was formerly believed that, once established, the hypersensitivity persisted essentially throughout life and that the tuberculin reaction was of limited value in the adult. It is becoming apparent, however, that reversion is more frequent than had been generally realized, particularly with reduction in the prevalence of the disease and therefore the risk of reinfection. ⁵⁸

The tuberculin test in cattle has great diagnostic importance and has been widely used in the United States and to a lesser extent elsewhere. Three types of test may be used in cattle: the intradermal test; the ophthalmic reaction of Calmette, in which tuberculin is dropped into the conjunctiva and the reactive animal responds with the development of a diffuse congestion and edema in six to eight hours which fades away in 24 to 36 hours; and the constitutional reaction as indicated by a rise in temperature following the injection of tuberculin. The intradermal inoculation into the skin of the caudal fold is generally practiced in this country.

The therapeutic value of tuberculin may be directly observed in lupus or tuberculous infection of the skin. As indicated above, there is a reaction about the foci of infection manifested as acute congestion and sloughing off of tissue. When it was first introduced, tuberculin was regarded by many as a highly effective specific therapeutic agent for tuberculosis. Its use is, however, exceedingly dangerous, and, with the exception of lupus, the response of tuberculous infection to the injection of tuberculin has been disappointing.

The mechanism of immunity. Infection with the tubercle bacillus confers a definite protection against reinfection, an "immunity to superinfection" resembling that observed in syphilis. The factors involved are as yet obscure. Some current opinion favors the view that the development of an allergic state is indicative of an effective immunity. It is commonly observed that in individuals giving a positive tuberculin reaction living cells are usually free of tubercle bacilli and the bacteria are present in necrotic areas separated by an avascular barrier, while in the infected individual giving a negative reaction, tubercle bacilli are found in great numbers in living tissue. The antibodies produced are apparently not

significant and antiserums have no protective or curative properties. As indicated above, the development of hypersensitivity is the most obvious response to infection, and there is no doubt that hypersensitivity plays a part in acquired resistance as indicated in Koch's early experiments. Its relative importance is, however, not at all clear, and the mechanism of what seems to be a low-grade immunity of short duration remains at the moment largely a matter of speculation.

Active immunization. The possibility of active immunization to tuberculosis has been of great interest since the discovery of the tubercle bacillus. In general, two types of vaccines have been employed, suspensions of living attenuated bacilli and suspensions of killed bacilli. 116

The attenuated bovine strain of Calmette, BCG, has been regarded as the most promising immunizing agent and has been extensively studied. It was originally given as an oral vaccine in France in the early 1920's. However, the combination of inadequate statistical data and an incident in Lübeck, Germany, in which a virulent strain was inadvertently substituted for the vaccine strain, resulting in tuberculosis in inoculated persons, put it into disrepute. Nevertheless immunization with BCG was further studied in the Scandinavian countries, beginning in 1925 in Sweden and in 1927 in Norway and Denmark. The freshly prepared vaccines have a relatively short. useful life, perhaps seven to 10 days, but lyophilized vaccines, stabilized by the addition of dextran146 or glutamate93, 158 after an initial loss of some viability, are stable for a year when stored at 20° C. or less. A heat-stable vaccine, stable for considerable periods without storage at refrigerator temperatures, has been developed.147 The vaccine is given intracutaneously in doses of 0.05 to 0.15 mg., and a positive tuberculin reaction appears in six to 10 weeks in over 90 per cent of those inoculated. The hypersensitivity lasts about four years, though in some persons there is reversion in as little as one year. On the assumption that a positive tuberculin reaction is indicative of immunity, reversion is taken to mean that reinoculation is required.

There is a large body of evidence^{9, 136} which supports the conclusion that such immunization gives an appreciable degree of protection against childhood tuberculosis,

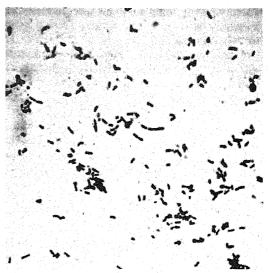

Figure 181. Avian tubercle bacillus. Acid-fast stain of a smear from a pure culture. × 1050.

but whether against infection later in life is not so clear. It is believed by some, 89 however, that the immunization, involving the use of a living vaccine whose virulence may not be fixed, is a dangerous one, and that confidence cannot be placed in immune response of the newborn and immature infant; fatal cases of infection with BCG have, in fact, occurred, 82, 152 but it is surprising that there have not been more in view of the many thousands of inoculations that have been carried out.

Immunization has been very generally applied in Scandinavian countries (where its effect on the decline in tuberculosis is probably overestimated), less so in Europe, and in only a restricted way in this country. While a general program of immunization may serve as a control measure in areas in which the disease is widespread and the general application of chemotherapy, isolation, etc., is not practical, 105 it appears to have only limited utility, as in groups exposed to unusual risk of infection, in this country. 46, 104

Pathogenicity for lower animals. Tuberculosis of lower animals living under natural conditions is probably very rare. Animals in captivity, however, may contract the infection with some facility; in animals kept in zoos and in monkeys kept in the laboratory for experimental purposes tuberculosis is not uncommon. Domestic animals may be similarly affected. A wide

variety of animals may be infected experimentally with one or another of the types of tubercle bacilli.

Domestic animals. The most commonly infected domestic animals are cattle, pigs, and chickens. Cattle are infected with the bovine type of tubercle bacillus almost exclusively; they are not completely resistant to the human type, as Koch originally thought, but infection is accomplished with some difficulty. The proportion of cattle infected increases with advancing age and, in the absence of control measures, may reach 70 to 90 and possibly 100 per cent in animals kept in stalls. The natural infection is generally of a chronic, slowly progressive nature. The lymphatics are most frequently involved and may be the only tissues to show lesions: the lungs are also commonly affected. Lesions on the pleura have a peculiar characteristic appearance, the so-called perlsucht disease. The liver, spleen, and kidneys are less frequently involved, infection of the mammary glands is not uncommon, and tubercle bacilli may be excreted in the milk in the absence of detectable lesions of the mammae. Congenital tuberculosis in cattle occurs with some frequency. In this country tuberculous infection in cattle is rigorously controlled; over nine million cattle are tested annually, and the percentage of infected cattle found is 0.19 and of infected herds 1.4 to 1.6.

Tuberculosis in chickens is very common and is exclusively an infection with the avian variety of the tubercle bacillus. With the exception of parrots and certain birds of prey, birds are highly resistant to infection with the human and bovine varieties, and it is probable that natural infection with these types rarely if ever occurs. Tuberculosis in chickens is usually a chronic process and is characterized by the formation of nodules in the abdominal viscera. The lungs are less frequently affected.

Pigs suffer from natural infection with both bovine and avian tubercle bacilli derived from infected cattle and poultry; they are also susceptible to infection with the human variety. In young pigs infection with bovine bacilli is generalized and acute with lesions in the lymphoid tissue, abdominal viscera, and lungs. Infection with the human bacillus is generally localized, but the avian type may produce a generalized infection.

Other domestic animals suffer from tuberculosis to a considerably lesser extent. Horses, dogs, and cats are occasionally infected, and the disease is rare in sheep

and goats.

Experimental animals. Experimental animals vary in their susceptibility to the varieties of the tubercle bacillus and in the type of infection produced. The guinea pig is highly susceptible to both bovine and human bacilli, and death follows the subcutaneous injection even of small doses in six to 15 weeks. The lymphatic glands, spleen, and liver are most affected, the lungs only slightly, and the kidneys never. The necrotic areas in the spleen and liver are the most striking feature of the gross pathology and are peculiar to the guinea pig. True tubercles are seldom seen except in the very early stages of the disease.

Rabbits are highly susceptible to infection with the bovine bacillus, somewhat so to the avian bacillus, and quite resistant to the human variety. Injection of bovine bacilli produces a generalized infection that terminates fatally in two to three months. On autopsy tubercles may be found in the spleen and liver, but the lesions are most marked in the lungs and kidneys and may even be confined to them. Very large doses of human bacilli (10 to 50 mg. intraperitoneally) may produce a progressive infection but not the acute fatal miliary disease. The mammalian tubercle bacilli, indistinguishable by cultural or serological methods, may, then, be

sharply differentiated by their pathogenicity for these two experimental animals.

Neither rabbit nor guinea pig is particularly susceptible to infection with the avian bacillus, though avian tuberculosis may be produced in the rabbit.⁴² In the guinea pig death may be produced by large intraperitoneal doses, but on autopsy macroscopic tubercles are not visible; cultures and smears of the liver and spleen, however, show the presence of the bacilli. This form of tuberculosis, the proliferation of the bacilli without macroscopic tubercle formation, is known as the Yersin type of tuberculosis.

Experimental infections of mice inoculated with the human variety of tubercle bacilli have been studied at length by Youmans and his co-workers. 167, 168 They have found that the median survival time of the infected animals is a linear function of the logarithm of the dose and that the generation time of the tubercle bacillus is four to six days *in vivo* in this animal as compared to 14 hours *in vitro*. These precise studies have made the mouse a valuable experimental animal, and it has been used extensively in work on chemotherapeutic drugs.

Epidemiology. 44, 55, 160 In man tuberculosis is largely an airborne infection. Dissemination by milk is now of relatively minor importance in the United States. The disease is one of civilization in that its transmission is facilitated by close contact. The frequency of positive tuberculin reactions rises rapidly from zero in the newborn through puberty, and many adults have been infected at one time or another. In most instances clinical tuberculosis has not occurred and the lesions have healed. The proportion of persons with active clinical tuberculosis is not known; in some investigations the ratio of cases to deaths has been found to be as high as 10:1 or 12:1, but the ratio of reported cases to deaths is not much more than half of this. The prevalence of tuberculosis, then, defies precise definition. Active tuberculosis, as found at autopsy, is also appreciable; in 1960 4:4 per cent of the cases in New York, and in 1963 10 per cent of the cases in Baltimore, were reported only after death. 129

There are marked racial differences in the prevalence of tuberculosis. The death rate of Negroes in this country is considerably higher than that of the white population, though the incidence of clinical tuberculosis in the two races is not greatly different. Whether this higher death rate is a consequence of environmental conditions or

whether it is in part attributable to racial differences in susceptibility has been a point of considerable interest. In this connection the experience in the United States Army is of particular interest. In the years 1922 to 1936 the average white morbidity rate was 2.10 per 1000 and the Negro rate 2.56, a ratio of 4:5; the white death rate was 0.24 and that of the Negroes 0.99, a ratio of 1:4; and the case-death ratios were 8.75 for the whites and 2.61 for the Negroes. Under the controlled conditions prevailing - i.e., preliminary physical examination, age, and sex selection, the same housing conditions, and identical diagnostic and therapeutic facilities -it would appear that though the incidence of clinical tuberculosis is not greater in the Negro, the disease is more frequently fatal. and the indicated greater susceptibility is a consequence of racial rather than environmental factors. During World War II the Negro, while making up but 10 per cent of the United States Army, contributed 43.4 per cent of the total deaths from tuberculosis. There is some evidence that less well-defined races of man differ in their resistance to tuberculosis: Jews and Italians appear to be more resistant than the Irish.

Tuberculosis has been decreasing at a steady and relatively rapid rate since 1850 or thereabouts as indicated by the decline in the death rate from this disease.^{38, 65} As in the case of some other diseases, the decline set in before the discovery of the bacterial etiology of infectious disease and the development of preventive measures, and hence is by no means entirely attributable to the practice of preventive medicine.

This decline has not been relatively the same in either the various age groups or in the two sexes. The death rate is highest in the very low age groups, that of one to two years, and falls rapidly in the five to nine group and then rises to a peak in early adult life, 20 to 24, and declines with, in recent years, a small secondary peak between 45 and 54 years (late adult tuberculosis). The decline in tuberculosis in the present century has been relatively greatest in the very young, an undoubted consequence of preventive measures.⁴⁰

The sex distribution of the death rates from tuberculosis in the various age groups is a curious phenomenon which has not been explained. The death rate for males of all ages is somewhat higher than that for females. In young adults, i.e., the 15 to 29 age group, the female death rate is consid-

erably higher than the male death rate. In the higher age groups the male death rate becomes proportionately greater and exceeds the female rate for the rest of life. In the present century the female death rate in the higher age groups has declined somewhat more rapidly than the male death rate.

There is no simple explanation for the observed decline in tuberculosis mortality. Probably the isolation of active cases to reduce the source of infection, together with improvement in living conditions, both environmental and nutritional, has played a significant part. Such a decline is usually taken as a manifestation of the inability of a disease to reproduce itself and leads to the prediction of its eventual disappearance. This need not necessarily follow, however, and in this country the number of new cases reported has increased since 1940. For example, between 1940 and 1947 the number of deaths declined by 20 per cent, while the number of new cases reported rose from 100,772 in 1940 to 133,837 in 1947 and then declined to 55,494 in 1960.

In this country, England, and the Scandinavian countries there appears to be a reservoir of minimal undiagnosed active tuberculosis of the late adult type concentrated in the age groups over 45 that is increasing.86, 107, 112 In New York City, for example, the proportion of new cases and deaths in persons over 45 doubled in the 20-year period prior to 1950, and 65 per cent of all deaths were of persons over 45. of whom 85 per cent were male. If this represents a residual of higher rates in earlier life, it will eventually decline, but if it is a consequence of suppression of the disease in otherwise susceptible persons by environmental factors, the reservoir of such persons may increase. It represents a source of infection to a population becoming increasingly more susceptible as a consequence of reduction in immunizing infections.

MYCOBACTERIUM LEPRAE (Hansen's Bacillus)^{26, 61, 68}

Like tuberculosis, leprosy is an old disease of man. The first accurate description of the disease in India was in the Sushruta Samhita about 600 B.C.; 130 it was known in Egypt in the time of the Pharaohs, and in China in the fifth century B.C. Perhaps more prevalent in ancient times, it is now most common in

Central Africa, India, Japan and other Asiatic countries, and the South Pacific. The disease is prevalent in South America, with endemic centers in Brazil, Colombia, and Argentina. It is estimated⁸ that there are 80,000 cases in Brazil, 50,000 in Mexico, 16,000 in Argentina, 12,000 in Colombia, 10,000 in Paraguay, 6000 in Cuba, and 3400 in Peru. It is relatively uncommon in Europe, and sporadic cases occur in Latvia, Estonia, and southern and eastern Russia, and on the Mediterranean coast. The total number of lepers in the world is not accurately known; estimates vary from two to seven million.

Leprosy has been introduced into the United States with varying consequences. In Louisiana, Florida, and Texas the imported cases have established foci in which the disease has a tendency to perpetuate itself, while in California and the central northwestern states it tends to die out. Elsewhere in the country transmission is so rare as to be negligible. It is estimated that there are 500 to 1000 lepers in this country, many of whom are segregated in the National Leprosarium in Carville, Louisiana, the remainder living for the most part in California and New York.

Bacilli were found by Hansen in 1872 in the round epithelioid cells generally known as lepra cells, and the observation was one of the first of pathogenic bacteria.

and staining. 132 Morphology Morphologically the leprosy bacilli closely resemble the tubercle bacilli. They are long (6μ) , slender rods, usually straight, but sometimes slightly curved, and club-shaped forms are found occasionally. 159 They are nonmotile and do not produce spores. They generally occur within the cells but are sometimes found free in the lymph spaces. Their arrangement within the cells is characteristic. several bacilli being usually grouped together in bundles like packets of cigarettes. Capsules are present on cells which are presumed to be viable, but are destroyed by the use of hot carbol-fuchsin for staining.53

The staining reaction of these microorganisms is much like that of the tubercle bacilli. They stain somewhat more readily than the latter, and also decolorize more quickly with acids, but the difference is not great enough for differentiation. The presence of large numbers of bacilli within the cells, together with the clinical features of the disease, makes it possible to distinguish leprosy bacilli from tubercle bacilli without difficulty.

以分辨的synt7

Because of their acid-fast staining characteristic and their morphological resemblance to the tubercle bacilli and similar bacteria, these bacilli are included with the mycobacteria designated *Mycobacterium leprae*.

Cultivation. Numerous unsuccessful attempts to cultivate Hansen's bacillus on artificial mediums were made for years by bacteriologists all over the world. A few investigators have reported positive results. In most instances acid-fast bacilli have been cultivated, but in others a variety of microorganisms, including diphtheroids, actinomycetes, and anaerobic bacilli, have been found. It has been suggested by some workers that the acid-fast bacilli present in leprous lesions represent but a single stage in a developmental cycle and that outside the body other forms appear. There are at present a number of cultures in various laboratories labeled Myco. leprae. It seems highly probable that none of these bacteria are leprosy bacilli in that they are etiologically related to the disease in man. They are very likely best grouped with the saprophytic acid-fast forms such as the smegma and timothy bacilli.

Among the more recent studies on the isolation of leprosy bacilli are those of de Souza-Araujo, 134 who has isolated acid-fast bacilli that have produced suggestive reactions on inoculation into monkeys. Freire 49 has cultivated similar bacilli in slide cultures. There have been a number of reports of cultivation, *i.e.*, persistence with apparently a few cell divisions, in tissue culture. 5, 37, 101

Pathogenicity. Although any organ or tissue in man may be attacked with varying results, two distinct types of leprosy are usually recognized—the nodular and the anesthetic. The former, which is the more acute, is characterized by the development of masses of granulation tissue, the so-called leproma, which may appear superficially in different parts of the body and by their growth and coalescence produce distortion and mutilation. The anesthetic type, or nerve leprosy, progresses more slowly, the average duration of the cases being nearly twice as long (18 years) as cases of the nodular type, some being known to extend over 35 or 40 years. Atrophy of the muscles and other trophic disturbances accompany the nerve

In both forms of leprosy Hansen's bacillus is found in all cases, in enormous numbers as a rule in the lesions of nodular leprosy and less abundantly in the anesthetic type. Very

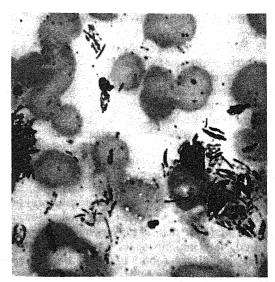

Figure 182. The leprosy bacillus. Acid-fast stained smear from a skin lesion. Note the characteristic tendency to parallel arrangement of the bacilli in packets. \times 1800.

few bacilli are observed outside the body cells, and they are found in the cytoplasm and do not invade the nucleus. Almost any part of the body may be the site of leprous growth; the kidneys are usually invaded, the liver and spleen always. The bacilli have been seen in the central nervous system and are occasionally found in the blood, generally in the leucocytes but sometimes free. There are a number of classifications of the clinical disease. 14, 21, 71, 110

Experimental infections. Until relatively recently it has not been possible to produce lesions with multiplication of leprosy bacilli in experimental animals by inoculation of leprous material. It has been found that inoculation of the footpads of mice results in an increase in numbers of the bacilli over relatively long periods of time. 123 The infection is transmissible and is inhibited by prior im-

munization with BCG126 or with antituberculosis drugs. 127 This experimental infection in mice has been confirmed by some, 96 but not by others. 67, 68 Similar infections have been produced in hamsters. 32, 153, 154 in the ears as well as footpads, and there is evidence that the optimum temperature for growth of the bacilli is less than body temperature. 125 It has been suggested that past failure to produce experimental infection by the inoculation of human leprous material was attributable not only to unfavorable temperatures in the deeper tissues, but also to the use of material from the tuberculoid or lepromatous types of the human disease. Such material may largely contain fully matured, terminal forms of the bacilli rather than bacilli, as found in borderline cases, more readily adaptable to another host.31

Transmission. Leprosy is probably transmitted by contact, though the conditions that make transmission possible are entirely unknown. There are numerous instances in which healthy persons, such as asylum attendants, have been more or less in contact with lepers for long periods without contracting the disease. In other cases, however, leprosy has been contracted by those in close and long-continued contact with diseased individuals. There is also indirect evidence of transmission. Manson cites the case of an Irishman who acquired leprosy in the West Indies. On his return to Ireland his bed was shared by his brother who, moreover, sometimes wore the leper's clothes. The brother. who had never been in any foreign country. became in time an undoubted leper. In this instance communication from one person to another was practically demonstrated.

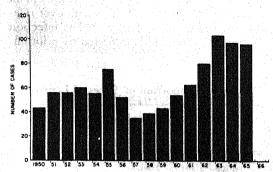

Figure 183. Cases of leprosy reported annually in the United States in the period 1950-1965. (Morbidity and Mortality Weekly Report, Annual Supplement, Vol. 14, No. 53. Communicable Disease Center, Public Health Service, U. S. Department of Health, Education, and Welfare.)

A large percentage of cases studied in Hawaii gave a history of exposure, and usually such exposure was of an intimate character. Leprosy occurs for the most part in populations of low social order living under unsanitary conditions of poverty, crowding. uncleanliness, and sickness. Even so, a relatively small proportion of those exposed develop the disease, and conjugal leprosy is unusual.85 Age at the time of exposure is important, the risk being greatest for those exposed before five years of age. Of children of lepers who are separated from their parents and who develop leprosy subsequently. the disease appears within the first year in 50 per cent, and in 90 per cent within three vears, after the last exposure.97

The bacilli may often be found in nasal secretions in analogy to tuberculous sputum. Although there has been some tendency to discredit nasal mucus as a source of infection, more recent studies indicate the importance of such secretions, the numbers of leprosy bacilli excreted per day approximating those of tubercle bacilli in sputum. 124 Whether the nasal area represents a primary site of infection is another matter. 16 For diagnostic purposes not only nasal smears. but scraped incision skin smear^{51, 66, 95} from a number of sites, as carried out at Carville, is preferable, and may allow the diagnosis of grossly inapparent infections. 60

Evidence of the direct inoculability of

leprosy from man to man is quite inadequate. Many attempts to infect healthy persons have been made and have failed, and one often cited instance of successful inoculation is by no means unimpeachable. In the case of the criminal Keanu in the Hawaiian Islands, reported by Arning in 1893, implantation of material from a leprosy nodule was followed by the development of true leprosy. which terminated fatally six years after inoculation. The experiment, however, did not include the important source of error involved in the facts that Keanu was a native of a country in which leprosy was common. that he had lived among lepers, and that members of his family were lepers. Later Lagoudaky⁷⁰ inoculated himself intramuscularly with blood from two lepers and contracted the disease.

Much light is thrown on the contagious character of leprosy by the success that has attended the isolation and segregation of leprous patients. The Norwegian experience showed that a careful but not unduly rigorous system of separation was accompanied by

a diminution of the number of cases from 2870 in 1856 to 577 in 1900 and to seven in 1964. 149 The circumstance that infection does not invariably follow chance contact or association should not, therefore, lead to the neglect of these facts: that leprosy is a bacterial disease; that up to the present under natural conditions the specific bacterium has not been found except in the human body; and that, so far as is definitely known, the leper himself is the most important means by which leprosy spreads.

Chemotherapy.^{24, 39} The similarities between the acid-fast bacilli observed in leprosy and the tubercle bacillus inevitably suggested the use of the drugs effective in tuberculosis in the chemotherapy of leprosy. Of these, the sulfones have been the most satisfactory, usually giving relatively rapid clinical improvement and slower bacteriological improvement. There is some tendency to relapse following cessation of chemotherapy. Diaminodiphenyl sulfone (DDS, Dapsone) is considered to be the chemotherapeutic agent of choice, and the activity of various derivatives seems to be attributable to the extent to which degradation to the parent compound occurs in vivo.

Made the Alley Details and the second of the second

The thiosemicarbazones appear to be reasonably effective but less so than the sulfones and are regarded as useful as an alternative when sulfones are not tolerated. Para-aminosalicylic acid has little chemotherapeutic activity, and preliminary studies with isonicotinic acid hydrazide have not been encouraging. Streptomycin has appreciable chemotherapeutic activity but has been found too toxic for the long period of administration required.

Immunity.²⁵ Man is highly resistant to infection with the leprosy bacillus, and, after infection is established, the ensuing disease is essentially a benign process that may take many years to terminate fatally; in fact, many lepers die from other causes. Little is known regarding the specific immune response. Lepels do, however, develop a hypersensitivity to the cell substance of acidfast bacilli such as the tubercle bacillus and the various saprophytic species. Muir⁸⁷ has suggested that the acid-fast bacilli exist as a continuous series with respect to parasitism, ranging from the saprophytic forms through the chromogenic forms occasionally found associated with the disease, the tubercle bacilli of clear host specificity, to

the first of the first state of the second sections and the second sections are second sections.

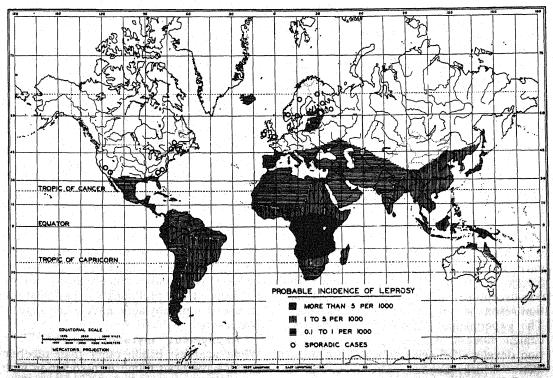

Figure 184. The probable prevalence of leprosy in the world. (Based on Goode Base Map No. 201 M. By permission of the University of Chicago Press.) (After Saunders.)

the leprosy bacillus which appears to be unable to live outside the host tissue. It is perhaps a consequence of the immunological relationships among the acid-fast bacilli that there appears to be a mutual exclusion between leprosy and tuberculosis. 15, 52 A curious fact is the appearance of a positive Wassermann reaction in lepers in the absence of syphilis, and both the Wassermann and the Kahn tests may be positive in lepers having no clinical symptoms of syphilis; moreover the serum of lepers is often anticomplementary.

Lepromin. 142, 143 The hypersensitivity developed by the leper may be demonstrated by the intradermal inoculation of material prepared from leprous nodules. Two reactions are observed, one early and occurring after three or four days, and the late reaction appearing three to four weeks after inoculation. The first is the Fernandez reaction and the second the Mitsuda reaction. The Mitsuda reaction is regarded by some workers as an expression of immunity, but it is nonspecific in that it occurs in tuberculosis and is induced by immunization with BCG.

MYCOBACTERIUM LEPRAE MURIUM

A native disease of wild rats, commonly known as rat leprosy, and characterized by enormous numbers of acid-fast bacilli present in the lesions, was described by Stefansky in 1903 as occurring in wild rats in Odessa. The disease was observed in the same year by Dean, who later showed it to be transmissible. It has since been observed in wild rats all over the world.⁴⁵

The acid-fast bacilli closely resemble the leprosy bacillus in size and shape and are found intracellularly but not as often in the packet arrangment of parallel bacilli. 19, 133 Myco. leprae murium has not been cultivated on artificial mediums64 but has been reported50, 54, 150 to persist through a few cell divisions in tissue culture. The disease may, however, be transmitted to white rats, mice, and guinea pigs by inoculation with pieces of tissue. Wild mice are relatively nonsusceptible, and subcutaneous inoculation results in only a transient granuloma.92 The experimental infection is a relatively benign process. A local, circumscribed lesion develops following subcutaneous inoculation which becomes palpable in four to five weeks and eventually develops to a large tumorous mass ulcerating on the surface and persisting throughout the life of the rat. The

earliest lesions in the other organs do not appear before four to six months, and the animal dies only after a year or more.¹⁸

The relation of rat leprosy to human leprosy is not known. Rats are not susceptible to inoculation with human leprous material.

OTHER ACID-FAST BACILLI

Mycobacterium paratuberculosis. A chronic enteritis of cattle usually terminating fatally is caused by an acid-fast bacillus closely resembling the avian variety of the tubercle bacillus. The disease is sometimes called Johne's disease and the organism Johne's bacillus after its discoverer. The disease only remotely resembles tuberculous infection. The lesions in the intestinal wall are proliferative, and the granulomatous tissue may contain epithelioid cells and occasionally giant cells, but there is no caseation.

The disease appears to be widespread in the United States. Infected cattle become hypersensitive to the bacillary substance, and filtrates of cultures produce a skin reaction analogous to the tuberculin reaction which is designated the "johnin reaction." No case of human infection with Myco. paratuberculosis has been recorded.

The vole bacillus. An acid-fast bacillus responsible for an epizootic, chronic infection of the field vole, Microtus agrestis, resembling tuberculosis was discovered by Wells in 1937. It closely resembles the tubercle bacillus culturally though it forms no pigment and growth is not enhanced by glycerol. It is pathogenic for both guinea pigs and rabbits, considerably more so for the latter, and is not pathogenic for fowls. It has been suggested that it is a distinct type of mammalian tubercle bacillus and should be called Myco. tuberculosis var. muris. This microorganism has been of particular interest because, though it produces only a localized and retrogressive infection when inoculated in small doses in guinea pigs and calves, tuberculin sensitivity is produced, and preliminary experiments on its use as a prophylactic have given suggestive results.

"Anonymous" mycobacteria. 20, 56, 63, 165
While acid-fast bacilli other than tubercle
bacilli have been found in association with
human disease from time to time, they have
been isolated more and more often within
the past few years and have attracted in-

creased attention. Because they are not identifiable with known species, they have been known as the "anonymous," "atypical," or "unclassified" mycobacteria.

These bacteria are found in man in the absence of disease, admixed with tubercle bacilli in tuberculous infections, and in large numbers in pure culture in apparently etiologic relation to tuberculous-like disease. The pulmonary disease^{33, 131} closely simulates tuberculosis, but endobronchitis seems to be more common, and there is somewhat more nonspecific inflammation and fibrosis. Similarly, the pathology of lymphatic infection, resembles that of tuberculous infection, including calcification in the later stages, but the infected nodes tend more often to be necrotic and suppurative in character.81 These infections are not common, and are reported to make up 1 per cent or less of suspected tuberculosis.

A granulomatous type of disease called "swimming pool granuloma" is well recognized and is attributed to the "cold-blooded" form *Myco. balnei*. The relationship of this microorganism to *Myco. fortuitum* of the atypical group IV (see below) is uncertain, ^{128, 141} as is that of *Myco. ulcerans*, the causative agent of necrotizing skin ulcer known as Buruli ulceration, found in Africa. ^{30, 98} Similarly, there are close resemblances between the "Battey" bacillus of group III and the avian tubercle bacillus. ^{13, 115}

These bacteria differ from the human tubercle bacilli in that they are not pathogenic for the guinea pig, are relatively resistant to the antituberculosis chemotherapeutic agents, grow more rapidly, and some are pigmented.^{28, 77} They are separated by Runyon into four groups, *viz.*:

Chromogens:

Group I. Photochromogens, producing a bright yellow pigment in the presence of light; many strains are pathogenic for man and the mouse; includes Myco. kansasii (Myco. luciflavum).

Group II. Skotochromogens (scotochromogens), producing a reddish-orange pigment independent of light; usually nonpathogenic for man or the mouse; includes *Myco. scrofulaceum*.

Nonchromogens:

Group III. Filamentous forms, possibly including some Nocardia strains; some strains pathogenic for man and the mouse; includes the Battey bacillus and Myco. (Nocardia) intracellularis.

Group IV. The "rapid growers," characterized by very rapid (2-4 days) growth; a few strains patho-

genic for man and the mouse; includes Myco. fortuitum.

These bacteria are immunologically related to the tubercle bacilli and other mycobacteria, 6, 166 and are considered by some 161 to have arisen from the former.

"Cold-blooded" mycobacteria. Acid-fast bacilli have been found associated with pathological processes in various cold-blooded animals. In some instances the processes superficially resemble tuberculous lesions. Myco. piscium was isolated from nodules and tumor-like formations in carp; Myco. marinum from "tuberculosis" of sea bass and certain other salt-water fish; Myco. ranae was found in the liver of a frog; Myco. thamnopheos is a parasite in garter snakes; and Myco. chelonei is the so-called turtle bacillus.

Saprophytic acid-fast bacilli. Included in this category are the well known timothy bacillus, Myco. phlei, found in soil, on grasses, and elsewhere in nature; the "butter bacillus," Myco. butyricum; and Myco. smegmatis, which is, however, a parasite found in both male and female smegma. The smegma bacillus is often difficult to distinguish from the tubercle bacillus on morphological grounds, and confusion of the two may have considerable practical importance in the diagnosis of suspected cases of tuberculous infection of the urinary tract. It is, it may be noted, also found in the urine and may contaminate fecal specimens. The saprophytic bacilli all grow much more rapidly than the tubercle bacilli, and neither they nor the bacilli isolated from coldblooded animals are pathogenic for guinea pigs and rabbits, or at best only feebly so.

THE PLANE WILL

Chapter Thirty-two

MEDICAL MYCOLOGY: THE PATHOGENIC FUNGI AND THE PATHOGENIC ACTINOMYCETES

By JOHN W. RIPPON, Ph.D.

The discovery of the causal relation of certain of the fungi to infectious disease preceded the pioneer work of Pasteur and Koch with the pathogenic bacteria by several years, for Schoenlein and Gruby studied the fungus causing favus (Trichophyton schoenleinii) in 1839, and in the same year Lagenbeck described the yeast-like microorganism of thrush (Candida albicans). Prior to this, Bassi described muscardine of silkworm (caused by Bauvaria bassiana). In spite of its earlier beginnings, medical mycology was soon overshadowed by bacteriology and has never received as much attention, though some of the fungous diseases are among the more common infections of man. This is perhaps attributable to the relatively benign nature of the common mycoses and the rarity of the more serious ones, and to the morphological basis of the differentiation of these structurally complex forms which, in a practical sense, sets them off sharply from the bacteria.

Even a brief consideration of the fungous diseases makes it clear that they fall into two well-defined groups, the superficial mycoses and the deep-seated mycoses. The superficial mycoses are by far the more common; are caused for the most part by a relatively homogeneous group of fungi, the dermatophytes; and include the various forms of tinea or ringworm, with infection of the hair and hair follicles, the superficial infections of the intertriginous or flat areas of the glabrous skin, and the onychomycoses

or fungous infections of the toe- and fingernails. In general, the lesions are mild, superficial, and restricted: the infections are almost never fatal, although invasion of the brain and heart by Trichophyton violaceum has been reported from Russia, Japan, and Roumania.8 The causative microorganisms are specialized saprophytes with the peculiar ability to digest keratin and which ultimately have their reservoir in soil; however, infections are frequently transmitted from one host to another. A yeast, Candida, also produces a dermatophyte-like disease. The deep-seated mycoses, on the other hand, are of sporadic distribution, being very common in some parts of the world and unknown in other areas, and are of heterogeneous etiology. They include histoplasmosis, aspergillosis, sporotrichosis, blastomycosis, coccidioidomycosis, cryptococcosis, and candidiasis (systemic) infections. The causative microorganisms appear to be soil-inhabiting saprophytes with peculiar abilities for adaptation to the internal environment of their host and are usually not transmitted from one individual to another.2 Infection by the organism in an endemic area may be very common however. Few infections develop into the severe, deep, spreading, and often fatal disease seen in some individuals.

A third group of microorganisms also treated in this chapter are the actinomycetes. These are bacteria which cause fungus-like infections and which were originally con-

sidered intermediate organisms. Morphologically, physiologically, and biochemically they are bacteria and are susceptible to antibacterial antibiotics; fungi are not.

Two of the diseases discussed in this chapter, actinomycosis and candidiasis, are caused by endogenous organisms, that is, species which are part of the normal flora of man; all other fungous and actinomycetous infections are exogenous in origin.

The criterion of pathogenicity is one of the poorest that can be used in the differentiation of microorganisms, not only because it is variable and difficult to determine, but because by its use parasitic microorganisms are grouped together that are, in fact, much more closely related to certain freeliving forms than they are to one another. The superficial nature of pathogenicity as a differential characteristic is nowhere better illustrated than among the fungi, for the pathogenic forms which constitute the subject matter of medical mycology form a heterogeneous group that includes some of the actinomycetes, certain molds and moldlike fungi, and a number of yeasts and yeastlike organisms. Of the nearly one hundred thousand species of fungi only a very few are known to be frequent infectious agents. of man and higher animals. With the possible exception of two or three dermatophytes, none of this group is an obligate parasite and most are misplaced soil saprophytes. The dermatophytes are frequently contagious, and man may serve as a disseminator of the species. Infection by the agents of the deep mycoses, however, seems to be accidental and is a blind alley, the parasite dying with its host. From a general biological point of view, then, the pathogenicity of certain fungi is of very minor significance; from that of the parasitized host, man, it is of considerably greater interest.⁷

The fungi are structurally complex, showing a variety of reproductive structures associated with sexual and asexual processes in addition to vegetative nonreproductive elements. Their differentiation into genera, species, and varieties is made in large part on a morphological basis,^{3, 4, 6} especially the morphology of the reproductive structures and, in contrast to the bacteria, their physiological and immunological characteristics are usually of minor or no importance for purposes of differentiation or identification. The biochemistry of the fungi, and of the molds in particular, has been extensively investigated in connection

Clinical Types of Fungous Infections

TYPE	DISEASE	CAUSATIVE ORGANISM	
Tinea versicolor Superficial infections Piedra		Pityrosporum orbiculare (Malassezia furfur) Trichosporon cutaneum (white) Piedraia hortai (black)	
Cutaneous infections	Ringworm of scalp, glabrous skin, nails	Dermatophytes. Microsporum, Trichophyton, Epidermophyton	
	Candidiasis of skin, mucous membranes, nails; sometimes generalized	Candida albicans and related forms	
Subcutaneous infections	Chromoblastomycosis	Fonsecaea pedrosoi and related forms	
	Mycotic maduromycosis	Allescheria boydii, Madurella myce tomi, et al.	
	Subcutaneous phycomycosis	Basidiobolus meristosporus	
Deep-seated	Histoplasmosis	Histoplasma capsulatum	
infections	Blastomycosis, North American	Blastomyces dermatidis	
	Blastomycosis, South American	Paracoccidioides brasiliensis	
	Coccidioidomycosis	Coccidioides immitis	
	European blastomycosis	Cryptococcus neoformans	
	Sporotrichosis	Sporotrichum schenckii	
	Aspergillosis Phycomycosis	Aspergillus fumagatus, etc. Mucor spp., Absidia spp., Phicopus spp.	

with the elucidation of decompositions occurring in nature and their application to industrial processes. Present knowledge of the respiratory mechanism of the cell and of alcoholic fermentation derives in very large part from studies of yeast. The immunological properties of the fungi have been little studied aside from noting the allergic phenomena associated with infection by certain of the dermatophytes and yeast-like fungi and frank allergy, i.e., asthma associated with fungal spores.

The skin test and complement fixation test, which are occasionally helpful in diagnosis, have been the subject of much investigation. Fungi are generally not good antigens and the role of immune mechanisms in

fungous disease is unclear. 133

The tissue response of the host to the offending agent varies widely with the variety of organism. In dermatophyte infections, erythema is generally produced and is probably a response to the irritation of the organisms or its products of metabolism. Occasionally, severe inflammation, followed by scar tissue and keloid formation, will occur. In organisms that invade living tissue, such as those responsible for subcutaneous and systemic disease, there is generally elicited a rather uniform acute pyogenic response. This usually gives way to a variety of chronic disease responses, listed in the accompanying outline. 19

Tissue Reactions in Fungous Diseases*

Chronic inflammation

Lymphocytes, plasma cells, neutrophils, and fibroblasts; occasionally giant cells

Rhinosporidium seeberi Subcutaneous phycomycosis

Pyogenic reaction

Acute or chronic, suppurative neutrophilic infiltrate

Actinomyces israeli sulfur granules
Nocardia astroides
Acute aspergillosis
Acute candidiasis

Mixed pyogenic and granulomatous reaction

Neutrophilic infiltration and granulomatous
reaction, lymphocytes, plasma cells

Blastomyces dermatitidis Paracoccidiodes brasiliensis Coccidioides immitis: neutrophils, especially at broken spherule

Sporotrichum schenckii: organism rarely seen in tissue

Chromoblastomycosis: chronic pyogenic, inflammation, epithelioid cell nodules and giant cells

Maduromycosis; in addition may be large foamy giant cells similar to xanthoma

Pseudoepitheliomatous hyperplasia

Following chronic inflammation in the skin hyperplasia of epidermal cells, hyperkeratosis, extension of rete pegs

B. dermatitidis
P. brasiliensis
Chromoblastomycosis
C. immitis

Histiocytic granuloma

Histiocytes frequently, with intracellular organisms sometimes becoming multinucleate giant cells

Histoplasma capsulatum Meningeal C. neoformans

Granuloma with caseation

Granulomatous reaction, Langhans' giant cells (L.G.C.), central necrosis

Histoplasma capsulatum Coccidioides immitis

Granuloma "sarcoid" type
Non-necrotizing

Cryptococcus neoformans Occasionally histoplasma

Fibrocaseous pulmonary granuloma; "tuberculoma"

H. capsulatum: thick fibrous wall surrounding epithelioid and L.G.C. organisms in soft center, often calcification

C. immitis: thin fibrous wall, rarely calcified

C. neoformans: poorly defined

Thrombotic arteritis

Thrombosis, purulent coagulative necrosis, invasion of vessel

Aspergillosis Phycomycosis

Fibrosis

Proliferating fibroblasts, deposition of collagen -- may resemble keloid

Loboa loboi

Sclerosing foreign body granuloma
In paranasal sinuses or viral infection

Aspergillus sp., bizarre hyphae in giant cells

Though a great many species of fungi have been described as pathogenic for man and animals, not all are of equal importance.

^{*}A Gram stain is used for actinomycosis, nocardiosis, actinomycotic mycetoma, and candidiasis; otherwise a PAS stain is recommended.

Some, especially among the dermatophytes, are not legitimate species different from those already known. Furthermore, in many cases the fungus described probably had no causal relation to the pathological process from which it was isolated, and in others only one or two cases of infection have ever been observed. It is sometimes very difficult to decide whether a fungus isolated from clinical material is of any importance. The accumulation of large numbers of species

of fungi and the minutiae of their morphological differentiation give medical mycology its complexity. Many skin, sputum, and air contaminants have been written into the literature as disease-producing organisms. Here we shall be concerned only with the more important fungi known to be causally related to human disease⁷; the remainder, though large in number, are associated with only a small fraction of the fungous diseases of man.

The Pathogenic Actinomycetes

The human pathogenic actinomycetes are so-called "higher" bacteria and are classified in the order Actinomycetales. This order includes some chronic disease-producing organisms such as the etiological agents of tuberculosis and Hansen's disease (leprosy). By tradition these last two organisms have been studied along with other bacteria. The remaining pathogenic actinomycetes, however, were thought to be transitional forms between bacteria and fungi and were included in the sphere of medical mycology. The etiological agents of lumpy jaw and actinomycotic mycetoma show some funguslike characteristics such as the branching of the organism in tissue, the extensive mycelial network that may occur in tissue or in culture, and the chronicity of the disease produced. However, cell wall analysis shows the presence of the typically bacterial muramic acid, which, along with the lack of a structural nucleus, typical bacterial size, and susceptibility to antibacterial antibiotics, defines these organisms as bacteria and not fungi. As far as their role as a phylogenetic "link" to the fungi is concerned, the presence of typical eucaryotic nuclei and mitochondria in fungous cells makes the derivation of the fungi from procaryotic bacteria independent of other eucaryotic organisms extremely improbable.

Morphology. The organisms grow in the form of fine straight or wavy nonseptate filaments or hyphae 0.5 to $0.8~\mu$ in diameter which show both lateral and dichotomous branching and which may grow out from the medium to form an aerial mycelium. On solid mediums the filaments occur in tangled masses, while in liquid mediums there is a tendency to centers or clumps of growth. There are three genera of medical interest: the anaerobic Actinomyces and the aerobic

Nocardia and Streptomyces.²³⁰ Classification of species within the genera and even separation of the genera themselves is controversial.²³¹ The following characteristics are generally accepted by workers in the field. Actinomyces includes organisms which are anaerobic or micro-aerophilic and nonacid-fast and in which the vegetative mycelium breaks up into bacillary or coccoid elements. The Nocardia are aerobic, sometimes partially acid-fast, and they fragment into bacillary or coccoid forms and produce chains of squared spores 1 to 2 μ long by simple fragmentation of hyphal branches.14 In Streptomyces there is more aerial mycelium, no fragmenting to bacillary or coccoid forms, and no acid-fastness, and chains of round to oval spores are produced consecutively within a specialized hyphal element. The maturation of the spore-bearing hyphae is often associated with the formation of spirals which range from open, barely perceptible coils to those which are so compressed that adjacent turns are in contact. The spirals may be dextrorse or sinistrorse; and both the direction and the tightness of coiling are constant within species. The spores are more resistant than the filaments and will survive 60° C. for as long as three hours, but are less resistant than bacterial spores. The tips of other filaments may become swollen and club-shaped. Segmentation of the filaments occurs in some species as early as 24 hours, while in others it is delayed three weeks or more; the segmented filaments fragment to form bacillary bodies 4 to 6 μ in length which are morphologically indistinguishable from many other bacteria. In most smear preparations of the pathogenic forms, the filaments are broken up and the appearance is that of ordinary bacilli. All, or practically all, of the actinomycetes are gram-positive, and some of the pathogenic forms are partially acid-fast.

Both spores and fragments of mycelium grow in subculture. On solid mediums the growth of the aerobic forms is dry, tough, and leathery, sometimes wrinkled, adherent to and piled above the medium; in many instances it resembles the growth of mycobacteria. In some cases the growth appears powdery or chalky, owing to the formation of aerial mycelium. In liquid mediums growth occurs in the form of a dry, wrinkled surface film or, more often, as flakes or aggregates which adhere to the sides of the flask, especially at the surface, or sink to the bottom.

Pigment formation, with colors ranging over the entire spectrum, is common among the actinomycetes, and differentiation is usually made between pigmentation of the vegetative mycelium and the spore-bearing aerial mycelium, as well as on pigment diffusing into the medium. Soluble purple and brown pigments are often observed on protein-containing mediums. The actinomycetes, especially the saprophytic forms, are physiologically active, utilizing a variety of carbon and nitrogen compounds, and many are actively proteolytic. An earthy to musty odor, like that of freshly turned soil or of a damp basement, is produced by many species. The optimum temperature for growth is usually 20° to 30° C. though some of the pathogenic species grow at 37° C., and thermophilic species, analogous to thermophilic bacteria, are known. The great majority of actinomycetes are aerobic, but some of the pathogenic forms are anaerobic or at least must be cultivated under reduced oxygen tension.

Differentiation of the actinomycetes from one another is determined in part on a morphological and in part on a physiological basis, the latter including pigmentation and proteolytic activity.

ACTINOMYCOSIS171

Lumpy jaw or actinomycosis was once a fairly common disease of cattle and occasionally of man. Today it is an uncommon infection, most often diagnosed in retrospect. This change is largely due to the widespread practice of giving antibiotics indiscriminately. The etiological agents Actinomyces israeli, A. bovis, and A. eriksonii are quite sensitive to most antibacterial antibiotics including penicillin and the sulfas. Formerly,

infection was often associated with tooth extraction or dental surgery, which provided traumatized tissue in which these endogenous organisms could grow. Prophylactic antibiotics following oral procedures have eliminated this hazard. Although the disease was undoubtedly observed early in the nineteenth century, actinomycotic tumors being described by Leblanc in 1826 under the name of osteosarcoma, it was first recognized as a specific parasitic disease by Bollinger in 1877. At his instigation the organism was studied by the botanist Harz, who described it and named it Actinomyces or ray fungus, because of the ray-like structure of its growth in the tissues, but he did not cultivate it. In 1891 Wolff and Israel isolated a micro-aerophilic actinomycete from pathological material by anaerobic culture, and in the same year an aerobic actinomycete was isolated by Bostroem from similar sources and named A. hominis (sometimes called A. graminis). Bostroem's organism has proved to be a contaminant, however, and it is definitely established that the organism isolated by Wolff and Israel was that observed by Bollinger and Harz and the etiological agent of the disease. These early observations were extended in large part through the work of Wright and Emmons, and summarized by Erikson. 54, 55

Presently, most workers agree that there are two commonly encountered species which cause the disease syndrome "lumpy jaw." A. bovis is the usual cause of actinomycosis in cattle and A. israeli the predominant organism in human infection although occasionally found in cattle. A. eriksonii, a new species, has recently been described in five cases of pulmonary actinomycosis without granule formation.

Morphology and staining. Actinomycosis is essentially a suppurative process characterized by the presence in the pus of yellow granules ("sulfur granules"), the drusen of German writers. These are, in fact, colonies of the bacteria which when examined microscopically are seen to consist of dense rosettes of club-shaped filaments in radial arrangement. The individual rosettes are usually 30 to 40 μ in diameter but sometimes are as large as 200 μ . The minute yellow granules, visible to the naked eye, may consist of a single rosette or may be made up of several. The rosette itself is made up of three kinds of structures: a central core of branching fialments, irregularly disposed but with a general radial

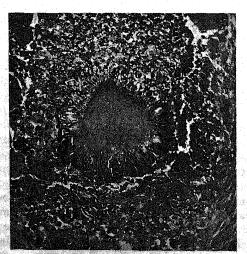

The Pathogenic Actinomycetes and Their Diseases

DISEASE	ORGANISM	GEOGRAPHIC DISTRIBUTION
Actinomycosis	Actinomyces israeli (man) Actinomyces bovis (cattle) Actinomyces eriksonii	Ubiquitous
Nocardiosis (pulmonary and systemic)	Nocardia asteroides Nocardia brasiliensis	Ubiquitous Mexico, South America Africa, India
Mycetoma (actinomycotic)	Streptomyces madurae Streptomyces somaliensis Streptomyces pelletierii	Ubiquitous Africa, Brazil, Mexico Africa, South America
Erythrasma	Corynebacterium minutissima	Ubiquitous
Cracked heel	Nocardia keratolyticus	India, United States
Trichomycosis axillaris	Corynebacterium tenuis	Ubiquitous
Epidemic eczema	Dermatophilis congolense	Australia, Africa, United States

arrangement; refringent, club-shaped bodies at the periphery radially arranged; and spherical coccus-like bodies. The granules may be crushed and examined in fresh preparations in which the clubs may be plainly seen, or a stain such as eosin may be used which colors the sheath of the clubs. The filaments are gram-positive, and the stain is useful for tissue sections; hematoxylineosin is quite satisfactory for sections. The organisms are not acid-fast.

The filaments of the central core are branched, are often curved, sometimes spirally, and are thickly interlaced in a network of mycelium. The individual filaments have a granular appearance and, particularly in older granules, segmentation and fragmentation are common, giving the filaments the appearance of chains of cocci. The individual filaments in these granules, as well as the filaments of Nocardia species and the various agents found in actinomycotic mycetoma, have an average diameter of $1~\mu$, or about the diameter of Escherichia coli. The filaments in tissue of fungus origin and the filaments in granules of mycotic mycetoma are about $4~\mu$ in diameter. This is a convenient method of assessing the category

olikadiki latta (111 merena mendelengak

Figure 185. Actinomycosis (A. israeli) granule in lung. Note the ray-like arrangement of club cells around the central granule. × 300. (Rosebury, Epps, and Clark.)

of disease with which one is dealing. Appropriate antibacterial or antimycotic therapy can be instituted before the specific etiological agent has been isolated and identified.

The club-shaped bodies at the margin of the granule are conspicuous by their high refringency and general structureless, homogeneous appearance. They are pear-shaped swellings of the terminal ends of the filaments and arise as distinct transformations of these. In young colonies the hyaline substance of which the clubs are composed is soft and may be dissolved in water, but as the age of the colony increases, the clubs become of firmer consistency. Their formation appears to be associated with the resistance of the tissues; when resistance to invasion is slight, they are absent, filaments alone being found. Clubs are, as a rule, more common in bovine than in human lesions.

The coccus-like bodies reported by various observers are probably of diverse nature. Such forms may result from the segmentation and fragmentation of filaments; in other cases they may be the ends of clubs appearing in the field of focus of the microscope.

A variety of other microorganisms will be seen in clinical cases of actinomycosis. These include various aerobic and anaerobic micrococci, diphtheroids, gram-negative bacilli, and fusiform bacilli, such as *Bacterium actinomycetem comitans*, which may be a symbiont of some strains of Actinomyces. It is probable that the Actinomyces sp. alone could not induce an infectious process, without the other associated flora.

Morphology in culture. The colonial morphology of A. bovis, A. israeli, and the

saprophyte A. naeslundi grown anaerobically on solid medium is sufficiently distinctive that, with experience and the use of selected physiological characteristics. the organisms can be differentiated from those of contaminating bacteria and from each other. After four to six days' incubation the colonies are often less than 1 mm. in diameter. At this time, all three organisms are usually opaque or dead white, or, rarely, show a slight gray or yellow tinge. A. israeli is generally a rough colony (R form) starting as a mass of branching filaments ("spider" colony or granular colony) with a lace-like border and developing into a lobulated, glistening, "molar tooth" colony. The S variant may be transparent, regular in form, and resemble A. bovis. In broth A. israeli grows slowly, forming a hard, granular, fuzzy-edged colony. A. bovis is generally a smooth (S) form in which colonies are at first dewdrop-like and later smooth, convex and with entire edges. The rare R variant may resemble A. israeli. In broth A. bovis produces a soft diffuse growth. The common mouth saprophyte, A. naeslundi, is generally smooth on agar and rapidly growing, with a diffuse or cloudy appearance in broth. It also grows aerobically after initial isolation; the others are micro-aerophilic after initial isolation. In physiological tests, A. israeli usually ferments xylose and mannitol, reduces nitrate, and does not hydrolyze starch; A. bovis hydrolyzes starch, does not reduce nitrates, and does not ferment xylose or mannitol; A. naeslundi reduces nitrate, but does not ferment xylose or mannitol. All three organisms are separated from anaerobic diphtheroids by their lack of

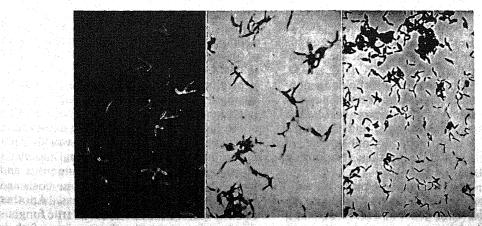

Figure 186. Actinomyces israeli. Left, darkfield. × 900. Middle and right; Gram stains of rough and smooth cultures respectively. × 1200. (Rosebury, Epps, and Clark.)

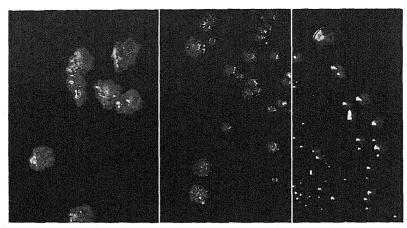

Figure 187. Colonies of Actinomyces israeli on brain-heart infusion agar after six days' incubation. Left, and center, rough "molar tooth" types. × 3. Right, colonies of the smooth type. × 6. (Rosebury, Epps, and Clark.) 188

catalase production. These procedures are discussed elsewhere.7

The essential features of the rosette or sulfur granule have been reproduced in cultures. The smaller colonies are rounded masses of branching and interlacing filaments. As the filaments become older they tend to fragment, and the largest colonies are dense opaque masses of short filaments and rod forms. Clubs are not formed in the usual mediums but only in the presence of blood, serum, or ascitic fluid, and even there develop inconsistently; it is generally agreed that club formation in tissue is in large part a host response. Stained smears of cultures show largely bacillary forms and a few fragments of branching filaments. The bacillary forms may be diphtheroid in appearance, they stain irregularly, and some have terminal swellings; the last are quite unlike the peripheral clubs of the actinomycetous granule.

Serology. By the use of the reciprocal agglutinin absorption method, and subsequently fluorescent antibody. Slack and his associates^{207, 208, 209, 210} separated the actinomycetes into four serotypes: A, B, C, and D. Kwapinski¹³⁵ in a series of articles demonstrated the antigenic relationship of A. bovis and A. israeli to Mycobacterium tuberculosis and various Streptomyces and Nocardia species. The serotypes do not appear to coincide with habitat, and their relationship to immunity is not known.

Pathogenicity for experimental animals. Attempts to infect experimental animals with A. israeli have, in general, been disappointlated animals develop the disease, and the

lesions are limited and benign. Some success has been found by traumatizing the tissue first and including the associated flora with A. israeli. Experimental infection with pure culture has been achieved by Meyer¹⁶⁰ in mice, using hog gastric mucin to enhance the invasiveness of the organism. Others have used repeated injections of the organism in rabbits and guinea pigs with less success. 75 In the experimental disease the essential features of the natural infection are observed, including the formation of tubercle-like nodules and the development of structurally typical granules with clubs.

Pathogenicity for man. 100 Infection with A. israeli during the first part of this century was diagnosed much more frequently than it is today and was, in fact, the most common fungous infection known. There has been a sharp decrease in the number of cases reported in the United States in contrast to the great increase in true fungous diseases. Probably the most important single cause in the decrease of actinomycosis is the widespread use of antibacterial antibiotics. Nichols and Herrel in 1948 reported on the successful use of penicillin in the disease, and this has been a standard therapy since that time. Another important aspect in the decline of infection is the high level of oral hygiene achieved in the developed nations of the world. That this is not the case in emerging nations is attested to by the continued numerous and increasing case reports of actinomycosis and related diseases in these areas. Another relative factor in the increase in true fungous ing in that only a small proportion of inocu- diseases is a better understanding of their etiology, incidence, and clinical course, as

695

well as the improved diagnostic methods available (when used).

NOCARDIOSIS

The disease in man differs in minor respects from that in cattle. Actinomycotic infections of the bone are relatively less frequent, the disease being confined to the softer parts in most cases. There is usually a lesser production of new tissue and a more extensive softening and suppuration. The disease falls into three clinical types. About 60 per cent of the infections are cervicofacial, and this type is often associated with dental defects or accidents and is a chronic. localized form of the disease which is relatively benign and usually susceptible to treatment. Some 14 per cent of the cases are thoracic infections, and 8 to 18 per cent are abdominal infections³⁴ in which the primary lesion is often in the appendix; in these types prognosis is poor. Draining sinuses are usually found in all types, and abcesses are frequently observed in the liver at autopsy. Generalization by hematogenous spread is occasionally seen and is relatively more common in man than in cattle. Meningitis, endocarditis, genital (both male and female) infections, and a syndrome-like mycetoma have been reported. The characteristic granules with clubs are usually found in the pus but may be absent occasionally in draining sinuses, especially when the infection has spread rapidly, particularly in meningitis and empyema. These latter types of disease may terminate fatally in a few weeks through secondary infection or formation of emboli, or may drag along in a chronic form for many years; spontaneous healing has been observed.

Immunity. Agglutinins, precipitins, and complement-fixing antibodies have been demonstrated in the serum of patients with actinomycosis. There is little or no evidence that they are involved in combating the disease or protecting the individual against the disease. Active defense against the organism is probably on a cellular level, and it has been suggested that the "clubbing" of the organism seen on the periphery of the granule represents a response to the cellular defense of the host.

Isolation and diagnosis. 82, 85, 100 As indicated earlier, the demonstration of the typical actinomycetous rosette or sulfur granule in the tissue or pus of a specimen is sufficient to establish a diagnosis of actinomycosis in man. Actinomycosis in cattle may be confused with actinobacillosis; the two are readily differentiated by examination of a

gram-stained smear for the presence of gram-positive diphtheroid-like fragments of Actinomyces filaments or of gram-negative actinobacilli. As may be inferred from the foregoing discussion, animal inoculation is useless as a diagnostic method. Cultivation of the bacteria is often, though not always, successful.

The procedure recommended by Wright for the isolation of A. israeli in culture has been widely used. Granules, preferably from a closed lesion, are thoroughly washed in several changes of sterile water or broth and then crushed between sterile glass slides. The material is inoculated into liquid (40° C.) 1 per cent dextrose agar in test tubes filled to a depth of 6 to 8 cm. After incubation at 37° C. for four to eight days, characteristic colonies develop, in greatest numbers in a narrow zone 5 to 12 mm. below the surface. These may be isolated from the shake culture in the usual way, washed in sterile water or broth is there is reason to suspect bacterial contamination, and subcultured in deep tubes of dextrose agar. Even in the absence of contamination the method is not particularly satisfactory and frequently fails.

Rosebury, Epps, and Clark 188 have shown that abundant and characteristic growth occurs on the surface of enriched agar mediums containing dextrose and incubated under anaerobic conditions in the presence of carbon dioxide. They recommend brainheart infusion containing 2 per cent agar. The granule, exudate, or other material is streaked serially on plates of the medium by means of a sterile bent glass rod, and the plates are incubated four to six days under anaerobic conditions in the presence of 5 per cent carbon dioxide. By this method A. israeli can be isolated even in the presence of heavy bacterial contamination.

NOCARDIOSIS²³³

Several species of aerobic actinomycetes are capable of causing human disease. ¹⁹⁸ All of these organisms are soil organisms and infection is endogenous. A possible exception to this is *Nocardia asteroides*, the etiological agent of nocardiosis. The organism has been isolated frequently in nature from soil, from infections in small animals and fish and as transient flora of the skin. Hosty et al., ¹¹⁰ in surveying the sputa from tuberculosis patients, examined over 85,000 specimens and found *N. asteroides*

in 175. A diagnosis of nocardiosis could not be established in these cases. Thus, the Nocardia might be considered as a saprophyte or minor secondary invader in these cases. Since these patients all had some lung disease, it is difficult to extrapolate to the normal population, as survey studies have not been adequate. It is suggested, however, that *N. asteroides* may be at least a transient member of normal pulmonary flora. Although pre-existing lung disease may favor a frank infection by the organism, this is not a necessary prerequisite.

The genus Nocardia was erected by Trevisan in honor of Nocard. Nocard had earlier described an aerobic, partially acidfast, branching bacillus from cattle as the causative agent of a disease called farcy. Some confusion exists concerning the name Nocardia farcinica, as used by Trevisan. Gordan and Mihm⁹³ suggest that N. asteroides be considered the type species of the genus and N. farcinica be reduced to synonomy with it. The name N. asteroides was first used by Blanchard in 1895 in referring to the Cladothrix asteroides of Eppinger. The first description of the disease in human patients was made in 1890 by Eppinger, who isolated an aerobic, branching, fungus-like organism from pulmonary and central nervous system lesions.

The genus Nocardia formerly contained various species isolated from the clinical entity mycetoma. Most of these species have been placed in the genus Streptomyces by MacKinnon¹⁴⁸ and are discussed under the heading Mycetoma. The remaining species, *N. brasiliensis*, is a common cause of mycetoma and is described with the other agents. This organism can also cause systemic nocardiosis.⁹²

There is a broad spectrum of disease elicited by N. asteroides infection. The variation probably reflects intensity of exposure to the agent and route of infection. Pulmonary disease is by far the most common manifestation of infection and varies from single lesions and scattered infiltrations to lobar consolidation and cavitation. The disease picture resembles that in tuberculosis, histoplasmosis, or other mycotic infections. Candida albicans superinfection may occur in this as in other mycotic diseases, and it is necessary to search thoroughly for an underlying agent.

Hematogenous spread of the infection may result in a secondary infection of the brain. Occasionally, there may be minimal infection in the lung, and the presenting symptoms are extrapulmonary. The kidneys, spleen, liver, and adrenals may be involved; however, in contrast to *A. israeli* infection, bony involvement is rare. The rare reported cases of *N. asteroides* mycetoma are difficult to assess, as there is no clear differentiation from *N. caviae*.⁸³

Serology and immunity. A skin test using a ground mycelial extract, nocardin, has been used with varied and limited success. An early preparation called asteroidin was reactive intradermally in infected experimental animals. Circulating antibodies have been reported, but their role in disease has not been assessed.

Pathogenicity for lower animals. The most frequently involved domestic animal is the dog. Similar types of pathology are seen in both animal and human infections. Cattle are also involved with infection, some in epidemic numbers. The relation of farcy of cattle to *N. asteroides* has been discussed. The organism also infects fish.²¹⁷

Isolation and diagnosis. In gross examination, lesion material cannot be differentiated from that in other infections of pyogenic bacteria. The tissue reaction, like that to A. israeli, is of the pyogenic type, acute or chronic suppurative with neutrophilic infiltration. The organism is best seen in tissue sections stained by the Brown and Breen modification of the Gram stain. The Gomori

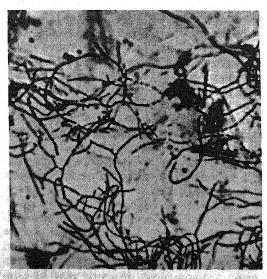

Figure 188. Nocardia asteroides. Gram stain of sputum. Note the long branched mycelium. \times 900.

697

methenamine stain is also useful. PAS and H and E are not helpful. Fine branching filaments, 1 μ in diameter, are seen coursing through the tissue. There is a lack of agglomeration or granule formation, as seen in A. israeli infection. Otherwise it is not possible to differentiate the two except by culture.

The organism grows well but slowly on all laboratory mediums and is usually not killed by the digestion procedure used on sputa for culture of tubercule bacilli. The classic colony is glabrous, wrinkled, folded, and bright orange. Variations from slick yeast colonies to dry powdery colonies with abundant aerial mycelia have been described. The color range recorded includes pink, lavender, salmon, white, buff, and brown.⁹³

Prognosis of the disease depends on early diagnosis and treatment. There has been a notable lack of success in established infections, especially those with extrapulmonary lesions. Sulfonamides are the favored drugs, especially sulfadiazine. Streptomycin, Aureomycin, and penicillin have also been used.

OTHER ACTINOMYCETOUS INFECTIONS

Erythrasma. This disease was first described by Burchardt in 1859, and the term erythrasma was used by Barensprung in 1862. Skin scales examined by these authors showed delicate filaments which were believed to be of fungous origin. They named the organism Microsporum minutissimum. In skin scales and on culture the organisms appear as gram-positive rods and filaments sometimes with granules. The scaling infected area of the patient and the colonies of the organism, when grown on tissue culture medium number 199 agar, show a coral red fluorescence which aids in its diagnosis. The disease itself is characterized by a punctate to palm-sized, well-circumscribed, maculopapular rash on the epidermis. The color varies from light brown to red or reddish brown. The advancing border is serpiginous and erythematous. The lesion is greasy looking and is covered with small furfuraceous scales. The most common form is genitocrural in the male, although other areas and other groups may be affected. Sarkany, Taplin, and Blank 195 found that infection of the toe web may occur in about one-fourth of the population. Systemic

erythromycin is the drug of choice. At present the organism is called *Corynebacterium minutissimum*.

Cracked heel (pitted keratolysis). This disease, also called keratolysis plantare sulcatum, was first described in India, but recently Zaias, Taplin, and Rebell²³⁷ have shown it to be of world-wide distribution. The etiological agent remains obscure but appears to be an actinomycete, either Nocardia or Micromonospora keratolytica. The bacteria appear to have a lytic action on the horny layer of the epidermis, and the disease is characterized by solution of the thick horny skin of the plantar surface in grooves. The skin cracks along these grooves to form deep fissures on the heel and in the thick sodden skin between the toes. These fissures extend through the corium to the subcutaneous tissues. Secondary infection is common. A similar disease, ulcus interdigitale, may occur on the toes. Treatment consists in good hygiene and the wearing of shoes.

Trichomycosis axillaris. This disease is characterized by yellow (flava), red (rubra), or black (nigra) concretions on the shaft of axillary or pubic hair. Perspiration in the affected area may be accordingly discolored and stain the clothing, this being the most common presenting condition. There is no other discomfort to the patient. Recently, an investigation of 100 consecutive patients revealed 28 cases of the flava variety without the patients' being aware of the infection.35 The disease may be more common than formerly considered. The organism has been named Corynebacterium tenuis and the flava variety will fluoresce. It is probable that a number of organisms are involved or are capable of producing the symptoms. Treatment includes depilation, alcoholic formalin solution 1 percent, and sulfur oint-

Streptotrichosis (epidemic eczema, contagious dermatitis). This disease was first described by Van Saceghem in 1915 as a skin disease of cattle. He named the etiological agent Dermatophilus congolense. Other isolates from cattle, sheep, deer and horses have been given different names, but Gordon⁹¹ concludes they are variations of a single species. The organism was first reported in the United States in 1961 and since has been reported from cattle, horse, deer, and man in Texas, Iowa, and New York. It now appears that the organism is of world-wide distribution, Roberts¹⁸⁵ be-

lieves the species to be a natural parasite of the epidermis of sheep.

Dermatophilis congolense grows in culture as a moist, lumpy, yellowish colony and microscopically as a branching mycelial mass in which the hyphal elements enlarge and go through a series of longitudinal and transverse divisions to form a motile coccal form. The motile stage formation is stimulated by low temperature, restricted nutrients, excess aeration, and moisture. The organism is a true epidermal parasite, normally not penetrating the dermal-epidermal junction. The disease in sheep is characterized by erythematous, exudative, scaling lesions which develop into pyramidal scabby masses. This condition is sometimes called lumpy wool. The organism is spread by contact and ectoparasites and is favored by cold, damp conditions.

MYCETOMA (Maduromycosis)27, 148

Mycetoma (fungous tumor) is a clinical syndrome which may have either a fungal or bacterial etiology. Though the mode of infection, type of tissue reaction, and general course of disease are similar, the choice of treatment depends entirely on knowing whether the infection is bacterial or fungal in origin. The first cases of this infection were reported from southern India (1842 et seq.) and became known as Madura foot. It is mainly a disease of tropical climates and appears usually in persons who do not wear shoes. The infection is frequently seen in temperate areas about the Mediterranean. in North Africa, Greece, and Italy. It also regularly occurs in Mexico, Central and South America, and the Caribbean Islands. Cases are sporadically seen in Europe and the United States. Most of the etiological agents are world-wide in distribution, but some are more common in one area than another, such as Streptomyces somaliensis in North Africa or Nocardia brasiliensis in Mexico.

The disease usually affects the foot, occasionally the hands, and more rarely other parts of the body. There are exceptions, as Nocardia brasiliensis is commonly associated with pulmonary infections. The organism presumably enters by traumatic implantation into tissue. There is some evidence that it may remain latent for some time. even a period of years, and become active following injury. The part first involved.

usually the sole of the foot, shows a small subcutaneous swelling which slowly enlarges and softens to become phlegmonous. It ruptures to the surface, sinus tracts form. and the process burrows into the deeper tissues, producing swelling and distortion of the foot; the bones may or may not be extensively involved. Numerous eminences are found on the surfaces, each the orifice of a sinus. The discharge is a viscid, slightly purulent, often foul-smelling fluid containing granular particles up to 1 mm. in diameter. The presence of these grains separates the mycetomas from pseudomycetomatous conditions observed in yaws, sporotrichosis, etc.

Examination of the granules will reveal whether the disease is one of the two types of mycetoma or is the mycetoma-like disease, botryomycosis, caused by Staphylococcus aureus. If the disease is mycetoma, careful examination of the granule (and subsequent confirmation by culture) will reveal which of the two groups is the etiological agent. The most obvious clinical difference in the mycetomas is the color of the grains present in the discharge. These may be white, yellow, red, or black. The grains or microcolonies are composed of mycelial filaments of the organism. One of the agents, S. madurae, has been shown to elaborate a powerful collagenase¹⁸² which may be involved in infection. 183 If the granule is composed of very thin $(1 \mu \text{ in diameter})$

intertwined mycelial elements, often with peripheral club cells, it is bacterial (actinomycotic mycetoma); mycelial elements more than 1 μ in diameter showing individual cells, septation, and usually chlamydospore production are found in fungous (mycotic mycetoma) infections. Actinomycotic mycetoma is treated with the usual antibacterial antibiotics such as penicillin, tetracyclines, sulfonamides, and diaminodiphenyl sulfone. Much less success has been observed in the treatment of mycotic mycetoma. Intravenous amphotericin B has been used, with remission of the disease in some cases. Iodides are still used with some success.

The disease is usually local, secondary abscesses seldom if ever occur, and the internal organs are probably never affected. In cases resistant to therapy or with extreme tissue destruction, surgical removal of the infected tissues, usually involving amputation, is necessary and curative. Occasionally the organisms associated with mycetoma

may be involved in quite different infectious processes, such as Allescheria in prostate¹⁵⁹ and eve⁵⁶ infections.

Laboratory diagnosis. As indicated above, the mycetomas are characterized by the presence of granules in the discharge. The grains may be hard and are usually treated with strong (20 per cent) sodium hydroxide to dissolve the pigment and debris and to permit examination in a wet mount (unstained) for the presence of tangled mycelial filaments. Clubs may be observed in actinomycetous infections, and thallospores (sclerospores), heavy-walled homogeneous structures, are found in Madurella and other fungous infections. For differentiation and identification, culture is necessary on enriched meat media (BHI agar) for actinomycetes, and Sabouraud's agar in the case of fungal etiology. Serology has been little used in mycetomas. Usually no antibody titers can be detected except in the more extensive infections, as occurs in N. brasiliensis pulmonary and systemic involvement.

The Pathogenic Fungi

The fungi proper, or Eumycetes, are quite distinct from the true bacteria, in size, cell structure, nuclear structure, and chemical composition. Differences in cell wall composition and nuclear structure were previously discussed, under the section on actinomycetes. Though essentially a single-celled organism, in some fungal species the cells may show various degrees of specialization. The simplest morphological form is the single-celled budding yeast; elongation of the cell without separation of new-formed cells results in a thread-like hypha; an intertwined mass of hyphae is called a mycelium. The mycelial mat is known as a thallus and, in most of the fungi discussed here, is a loose network of hyphae. In some higher forms, hyphae are cemented together to form large. structurally complex fruiting bodies such as the mushrooms and puffballs, which may weigh more than 60 pounds. Even though attaining such great size, all fungi are still primitive organisms: any separated single cell from a 60-pound puffball can regrow the entire structure. This ability separates the fungi, protozoa, and algae from higher forms such as trees and mammals.

Two main structural types of mycelium may be distinguished. In one of these the

cells making up the hyphae are not separated by cross-walls or septa, making possible the characteristic flowing of protoplasm through the multinucleate structure. Such a structure is said to be nonseptate or coenocytic. Certain of the algae are of similar structure, and the fungi thus characterized are called phycomycetes or algae-like fungi. In the majority of fungi, however, the hyphae are septate, each cell separated from the other by crosswalls. The septations have "holes" in them so that there may be free flow of cytoplasmic material. Nuclear migration is possible in the ascomycetes, which have a large pore in the intracellular septa. A special structure, comprising the dolipore and parenthesome, prohibits nuclear migration in the basidiomycetes. Each basidiomycete cell contains two dissimilar nuclei (dikaryon), one derived from one parent or mating type and the other from the other parent. The mycelium of this latter group may also show a special bridge structure connecting one cell to the cell next in line. This is called a clamp connection and is involved in nuclear transfer to a newformed cell. Thus these three main classes of fungi may be distinguished in part on the basis of the structure of the mature nonsporulating hyphae, though this is not one of the main characteristics upon which their differentiation is made.

The mycelium is further differentiated into two general types which differ in function. One of these, the vegetative mycelium. consists of masses of hyphae within the colony, adjacent to and growing into the substrate, and is concerned with the assimilation of food materials. Fragments of such mycelia will reproduce if transferred. The other type, the reproductive mycelium, usually extends into the air to form an aerial mycelium and gives rise to reproductive bodies or spores. The mode of spore formation and the structure of the spore and sporebearing elements are the characteristics by which the fungi are differentiated, classified, and identified.

In addition to sporulation and the vegetative growth of hyphae, many species of fungi reproduce by the separation of cells, known as oidia, from any part of the mycelium. These vegetative reproductive forms may give rise to new mycelium or reproduce themselves by budding like the yeasts, according to the environment in which they

are placed.

Spore formation. Two kinds of spores are to be distinguished, the sexual spores, which are produced by the fusion of two cells which may or may not differ, and the asexual spores, which arise by differentiation of the cells of the spore-bearing hyphae without fusion. If a sexual spore is produced only with a nucleus from another mating type, the fungus is said to be heterothallic. If any nucleus from within the same thallus will serve in forming sex spores, the fungus is homothallic. Fungi for which both sexual and asexual types of spore formation are known are "perfect fungi" and may be further differentiated on the basis of differences in the fruiting body that results from sexual fusion and differences in type, size, color of sexual cells, and other morphological characteristics. The three classes of fungi, based on the method of sex spore formation, are Phycomycetes, Ascomycetes, and Basidiomycetes. A fourth group is the formclass Deuteromycetes, or Fungi Imperfecti, for which no "perfect" or sexual state is known.

Sexual spore formation. The most common of the Phycomycetes are species of Mucor and Rhizopus. These molds produce a sexual spore known as a zygospore by the fusion of neighboring filaments of the same or different plants. The Ascomycetes, which include a number of genera as well as certain strains of Penicillium and Aspergillus, and also the yeasts, form sexual spores known as ascospores because they are contained in an ascus or sac. Their formation is simplest in the yeasts, in which two contiguous cells fuse by means of minute tube-like processes. The nuclei unite, and the resulting single nucleus divides several times to give four or eight daughter nuclei. Reserve material accumulates about each nucleus, a spore wall is formed, and the cell containing this is the ascus. In most of the Ascomycetes the process is somewhat more complex, and the cells which fuse may be distinguishable and are termed the oögonium and antheridium. The cell resulting from this fusion gives rise to new hyphae. It then goes through a complex structural development called crozier formation, with the next to last cell being binucleate. These nuclei fuse and then divide to form the ascospores, i.e., two nuclear fusions are involved in the entire process.

The basidiospores, the reproductive unit of the Basidiomycetes, are also formed by a complex process including clamp connection formation, by which one nucleus of a mated pair travels from one cell to a newly formed cell, the other nucleus going by the "center road" through the middle of the cell. The nuclei finally fuse in a club-like structure called a basidium and give rise to four externally attached basidiospores, two of the cells being the mating type of one parent and two the mating type of the other parent. Basidia line the gills of the mushrooms, are found in crypts inside puffballs, and line the pores in Boletes. So far, none of the Basidiomycetes has been shown to be pathogenic. The Ascomycetes include Piedraia hortae (black piedra), Allescheria boydii (mycetoma), and the dermatophytes (usually known by their imperfect name). The Phycomycetes are represented by Mucor, Rhizopus, Basidiobolus, etc. Many pathogenic fungi have no known sexual phase and are classed as Fungi Imperfecti.

Fungi Imperfecti. The "imperfect fungi" or Fungi Imperfecti (Deuteromycetes) are sometimes called hyphomycetes; they make up the fourth group of Eumycetes. The group is necessarily provisional, and various species of fungi are removed from it from time to time as their sexual phases are discovered. The classification of the organisms is based on asexual spore-type formation, color, shape, size, etc. Often an organism will be given a name based on its asexual characteristics before its sexual stage is known. Later, when a sexual stage is discovered, a name descriptive and taxonomically meaningful will also be given to it. This sometimes leads to two names for the same organism. It may be confusing at first, but it is taxonomically legal, for example, for the dermatophyte asexual phase to be Microsporum gypseum and its perfect state to be Nannizzia gypsea. To add to the confusion, the organism we call M. gypseum is the imperfect stage of two species of perfect fungi, N. gypsea and N. incurvata. This emphasizes the concept of Fungi Imperfecti as being simply a convenient descriptive filing cabinet for species waiting to be assigned to meaningful categories if only their sexual mechanisms can be discovered.

Microscopic examination. The methods used in the microscopic examination of the fungi vary somewhat according to the nature of the material and the purpose of the examination. In general, the staining methods so useful in the study of the bacteria are not applicable; the fungi are almost all grampositive and may be found in gram-stained smears, but their morphology is obscured. Wet mounts, unstained or lightly stained, are most informative.

Specimens. Open or draining lesions are almost always so heavily contaminated by secondary bacterial invasion that fungi are very difficult to find; in material from surgically opened lesions they are usually demonstrable though not so numerous as bacteria in corresponding bacterial infections. A simple method to show the yeast cells, mycetoma granules, or mycelial units in pus, exudate, or sputum is to treat the specimen with potassium hydroxide (KOH mount) in the manner described below. In the dermatomycoses, secondary bacterial infection ordinarily does not interfere with the microscopic demonstration of the fungous elements. The dermatophytes live in keratin material exclusively, and specimens should be taken from scrapings of horny layers, tops of vesicles, scrapings from nail plates, and hair.

The material should be mounted in strong (10 to 20 per cent) hot potassium hydroxide—which dissolves or makes translucent the tissue elements and bleaches the pigment in mycetoma granules but ordinarily affects the fungus more slowly—and examined as a wet unstained preparation. Antiformin or lactophenol may be used

instead of potassium hydroxide. Care must be taken to distinguish between spores and fat globules and between mycelium and fibrin strands; a mycelium-like structure ("mosaic fungus") may be formed in some skin scale preparations, presumably from cholesterol. Fungi may be demonstrated in tissue sections, as the walls of abscesses and granulomatous tissue, by the Unna-Pappenheim (methyl green-pyronine). Hotchkiss-MacManis (periodic acid-Schiff), Gridley (a modified PAS), or Gomori (methenamine silver) stain. Gomori's stain is recommended for finding the few organisms in a large specimen, and Gridley's for distinguishing the detail of fungus structure. Actinomycetes are not stained by these procedures; for these organisms the modified Gram stain of Brown and Breen is recommended

Cultures. A bit of growth is removed from the colony, teased apart in a drop of water, and examined as a wet preparation. While the various structures may be seen, the arrangement of the elements is seriously disturbed. Slide cultures show the structure and arrangement of the growth and may be made into permanent mounts. These are especially recommended for identification of dermatophytes; they are not recommended for Coccidioides, Histoplasma, etc.

Cultivation. 7 Most of the fungi grow rapidly, but the pathogenic forms usually grow relatively slowly: three or four weeks' incubation may be necessary. Their morphology is markedly affected by the type of medium on which they are grown. In general, they show no unusual nutritive requirements and grow readily on all the usual bacteriological mediums, especially if a sugar is added. Many molds tolerate a high acidity and may be cultivated on tartaric acid-dextrose nutrient agar, on which bacterial growth is inhibited. Most grow well on modified Czapek-Dox medium (a glucosenitrate synthetic medium), which is reproducible and has been widely used as a "standard" agar for descriptive purposes. Sabouraud's medium, a peptone-maltose agar, is perhaps the most widely used medium in medical mycology for the isolation and maintenance of cultures, especially the dermatophytes.

In present laboratory practice, antibiotics are added to make the medium selective for a particular group of organisms. For dermatophytes and the mycelial stage of the thermal dimorphic fungi, Sabouraud's medium

which chloramphenicol (against bacteria) and cycloheximide (Actidione), which suppresses most contaminant fungi, is very useful. Some pathogenic fungi will not grow on Actidione medium, e.g., Candida tropicalis, the yeast stage of Histoplasma and Blastomyces, and Cryptococcus neoformans; all actinomycetes are inhibited by the Chloromycetin. If these organisms are suspected, other culture methods must be used.

The fungi to be discussed in this section will be arranged as to the clinical location of their site of infection. 90 The categories are as follows:

Superficial mycoses: Only the outermost layers of skin or hair are involved and there is practically never any host reaction to the parasite, as in piedra and tinea versicolor.

Cutaneous mycoses: The infection is limited to the superficial layers of the skin with little or no invasion of living cells. There may be significant, and occasionally severe, host reaction to the presence of the organism. The dermatophyte and dermal Candida infections are included.

Subcutaneous mycoses: In this category are diseases in which the organism has invaded or has been implanted into subcutaneous tissue. Usually the infection is limited to the site of entry and a long clinical course may ensue. Chromoblastomycosis, mycetoma, subcutaneous phycomycosis, and sporotrichosis are examples.

Systemic mycoses: The most dangerous and often fatal disease-producing organisms are in this category. Entrance of the organism is usually through the lung, and the disease may spread to other parts of the body. The diseases of the thermal dimorphic organisms (histoplasmosis, blastomycosis), systemic candidiasis, coccidioidomycosis, cryptococcosis, etc., are discussed.

Rare mycoses: The mycoses that are not often encountered and the organisms not usually considered pathogenic are included. These may be soil organisms re ponding to an unusual environment after accidental implantation or invasion of a debilitated host. Such diseases as aspergillosis, phycomycosis, and cladosporosis are considered.

THE SUPERFICIAL MYCOSES

TINEA VERSICOLOR (Pityriasis Versicolor)

This is a common, world-wide fungous infection. It is most common, however, in

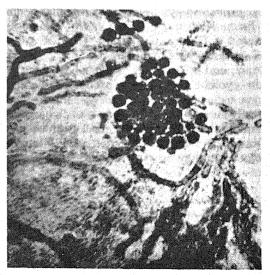

Figure 190. Skin scale from tinea versicolor. Short branched mycelium and small yeast-like cell are diagnostic of this disease. Methenamine silver: × 400.

tropical areas. The disease is characterized by yellow to brown patches or continuous scaling over the trunk and occasionally the legs, face, and neck. The affected area fluoresces a golden vellow when irradiated with a filtered ultraviolet lamp, "Wood's light" (peak at 3560 Å). Susceptibility is probably genetic and may be related to the rate of epidermal growth and desquamation. High endogenous or administered cortisone levels may also predispose to the disease.123 The etiological agent was called Mallassezia furfur in the older literature. There is considerable evidence that the organism is the lipophilic yeast Pityrosporum orbiculare. 131 It will not grow on ordinary mediums, usually requiring some lipid additives. Diagnosis is easily made by examining the scales in a KOH mount. Short, thick hyphal elements and associated round forms are seen. Successful treatment includes selenium sulfide shampoo and Whitfield's ointment. The infection usually recurs.

TINEA NIGRA

The disease tinea nigra makes itself manifest as dark blotches on the palms of the hands and rarely elsewhere on the body. In a KOH mount the organism appears as brown, branched hyphae, 2 to 3 μ in diameter. Though most common in the tropics, occasional cases occur in the United States. The etiological agents are members of the genus Cladosporium, which

is probably synonymous with the genus Hormodendrum. C. werneckii is commonly found in Central and South America, while C. mansonii is encountered in India, tropical Asia, and Africa. The colonies grow slowly on cycloheximide agar, producing a dark, greenish black, moist colony. Microscopically numerous, dark, one- and two-celled, budding conidia are seen on dark mycelium. Keratolytic fungicides, such as Whitfield's ointment, may be used in treatment.

PIEDRA

This disease is a fungous infection of the hair, characterized by nodules on the distal shaft. Two types are encountered. White piedra, in which soft light-colored nodules form, is principally found in temperate regions. The etiological agent, Trichosporon cutaneum, is sensitive to cycloheximide but will grow on most other mediums. It produces a soft, creamy, rapidly growing colony which becomes yellowish gray. Microscopically, it is composed of hyaline septate mycelium that fragments into oval arthrospores. T. cutaneum is separated from other members of the genus by its lack of fermentation of sugars, its lack of growth on potassium nitrate, and its carbon assimilation pattern. Black piedra is a hard, black or brown nodule caused by the ascomycete,

Figure 191. Black piedra knob on hair shaft. Piedraia hortae. × 100.

Piedraia hortae. This disease is mainly tropical, being found in Latin America, Asia, and Africa. It also infects other primates. The organism grows slowly on cycloheximide agar, producing a greenish to rusty black, hard, raised colony. The colony is composed of dark mycelium and chlamydospores. Asci are rarely seen in culture. Treatment consists in shaving off the hair.

THE CUTANEOUS INFECTIONS (Dermatophytoses)⁵

By far the most common type of fungous disease of man is dermatophytosis (dermatomycosis), a superficial infection of the keratinized epidermis and keratinized epidermal appendages, i.e., the hair, hairsheaths, and nails, the severity of which is dependent for the most part upon the location of the lesion and the species of fungus involved. Though certain other fungi, notably Candida, produce clinically similar disease, a more or less homogeneous group of fungi, the dermatophytes, is responsible for the great majority of cases. The ability of these microorganisms to invade and parasitize the cornified tissues is closely associated with, and dependent upon, their common physiological characteristic: the utilization of the highly insoluble scleroprotein keratin. The utilization of keratin is biologically rare and is shared by the dermatophytes (family Gymnoascaceae) with only a few species of saprophytic fungi (notably the family Onygenaceae) and certain insects including the clothes moth (Tinea), the carpet beetles (Dermestes), and the biting lice (Mallophaga).

Though the various species of dermatophytes produce infections that are clinically characteristic, on the one hand single species may produce different types of disease and, on the other, infections that are very similar or essentially identical may be produced by different species. Furthermore, other conditions such as chemical dermatitis, neurodermatitis, and certain types of allergy may closely simulate dermatophytosis, but do not, of course, respond to treatment with fungicides. Demonstration of the causative fungus by direct microscopic examination of pathological material or by isolation and culture is, therefore, highly desirable, especially in all cases presented for treatment.

The antibiotic griseofulvin has proved to be a highly effective chemotherapeutic agent for the treatment of the dermatomycoses, 106, 178, 179, 189, 238 but cure commonly requires prolonged (three to 10 weeks) administration by mouth. There may be severe side effects from the use of this drug. 191 The antifungal effect of the antibiotic is reflected in morphological changes in the infecting fungus, both *in vivo* and *in vitro*, and may be involved in utilization of keratin. A new drug, tolnaftate (Tinactin), has had promising results in most infections, except those of the hair and nails.

The dermatophytes were until recently classed as Fungi Imperfecti. Through the work of Stockdale,²²⁰ Gentles, and others, it has been demonstrated that many have a sexual stage (and hence a perfect state name). This observation was first made by Nanizzi in 1927 but was ignored. Consequently, many of the organisms are known by two names. In clinical dermatology the older imperfect stage name is still in common usage and probably will remain so. Most of the organisms shown to have a perfect state are heterothallic and will not show ascus formation except when grown with an opposite mating type. Even then, cleistothecia formation usually may occur only on mediums with a mixture of keratin and soil. A list of the known dermatophytes and their perfect stages is given below. Many related organisms have been isolated from the soil, but as yet have not been isolated from lesion material or only rarely.67

These organisms differ from most other

pathogenic fungi in that the cells are multinucleate, usually containing four to six nuclei, and division is amitotic. Arthrospores, chlamydospores, and the individual cells of fuseaux (macroconidia) are also multinucleate, but aleuriospores and microconidia contain but a single nucleus. The group is a homogeneous one, immunologically as well as morphologically and physiologically. Only recently have some physiological differences been found which are an aid in identification. These will be discussed later.

Differentiation of genera and species. 77, 141 David Gruby in 1841 described the fungal etiology of favus. Culturing the fungus from an infected lesion, he reproduced the disease by inoculation into normal skin. After this time, many fungi were isolated from similar lesions. Some were the responsible agents, many were contaminants, and practically all were given different names without regard to proper taxonomic procedures. Some order was brought about by the work of the French dermatologist Sabouraud. The classification of Sabouraud, presented in 1910 and somewhat modified by him later, is the most generally used. The system was extensively revised by Emmons⁴⁹ and Conant, who reduced to synonomy many varieties of the same species. Presently, work on the ascigerous state and physiological differences will help in establishing species lines. As of now, we are still dependent on differences in colonial and microscopic morphology, pigment, spore types, etc.

Colonial morphology is readily altered

The Ascigerous States of Dermatophytes and Related Species

IMPERFECT STATE	USUAL HOST	PERFECT STATE
Microsporum gypseum	Man, animals	Nannizzia gypsea Nannizzia incurvata
Microsporum fulvum	Man, animals	Nannizzia fulva
Microsporum nanum³	Pigs	Nannizzia obtusa
Microsporum cookei	Rare; man	Nannizzia cajetana
Microsporum vanbreuseghemi	Rare; man, animals	Nannizzia grubyia
Keratinomyces ajelloi	Rare; man, animals	Arthroderma uncinatum
Trichophyton terrestre	Rare; man	Arthroderma quadrifidum
Trichophyton mentagrophytes	Man, animals	Arthroderma benhameu

The Common Dermatophytes

			SPECIES	DISEASE IN MAN	GEOGRAPHICAL DISTRIBUTION
			Microsporum audouini	Prepuberal ringworm of the scalp; suppuration rare	Commonest in Europe, producing about 90 per cent of infections; in U.S. 50 per cent
	Small spore varieties		Microsporum canis	Prepuberal ringworm of scalp and glabrous skin; suppuration not infrequent; kerion occasional; from pets	Uncommon in Europe; responsible for about half the infections in U.S.
			Micropsorum gypseum	Ringworm of the scalp and gla- brous skin; suppuration and kerion common; from soil	Relatively rare in U.S.; common in South America
			Microsporum fulvum	Ringworm similar to that of M . $gypseum$	Same as above
			Microsporum ferrugeneum	Similar to M. audouini	Africa, India, China, Japan
and nair tourcies			Trichophyton tonsurans	Black-dot ringworm of scalp and smooth skin; sycosis; ony- chomycosis; suppuration com- mon; the hair follicles are atrophied	Common in Europe, Russia Poland, Italy, Near East, bu uncommon in U.S. until re cently
Invading the hair and ha		Endothrix type	Trichophyton violaceum	Black-dot endothrix in both scalp and smooth skin; onychomyco- sis; suppuration is the rule and kerion frequent	Common in Europe and Far East rare in U.S.
nding in	les	Endo	Trichophyton soudanense	Inflammation, scarring, ringworm of scalp	Central and West Africa
Inva	e variei		Trichophyton gourvilii		
000	Large spore varieties		Trichophyton yaoundi		
c I	E.J.	type	Trichophyton mentagrophytes	Commonest cause of intertri- ginous dermatophytosis of the foot ("athlete's foot"); ring- worm of smooth skin; suppura- tive folliculitis in scalp and beard	Ubiquitous
		Ectothrix type	Trichophyton verrucosum	Ringworm of scalp and smooth skin; suppurative folliculitis in scalp and beard; from cattle	Ubiquitous
			Trichophyton megnini	Sycosis is the most common lesion; infection of smooth skin and nails	Sporadic distribution; Sardinia Portugal
;	No Seroce	in hair	Trichophyton schoenleinii	Favus in both scalp and smooth skin; scutulum and kerion	Europe, Far East; rare in U.S.
Not invading the hair and hair follicles			Epidermophyton floccosum	Cause of classic eczema mar- ginatum of crural region; causes minority of cases of intertri- ginous dermatophytosis of foot; not known to infect hair and hair follicles	Ubiquitous, but more common i tropics
			Trichophyton rubrum	Psoriasis-like lesions of smooth skin; onychomycosis; mild suppurative folliculitis in beard	Common in Far East, tropic Europe, U.S.
N _{ot}			Trichophyton concentricum	Commonest cause of tinea im- bricata; infection of hair and nails uncertain	Common in South Pacific islands Far East, India, Ceylon; re- ported in South America; does not occur in U.S.

by continued culture on artificial media. In consequence many stock cultures of dermatophytes are atypical to a greater or lesser extent. Such variation is especially prone to occur on maltose "proof" agar, and Sabouraud recommends a milieu de conservation, the same medium but lacking sugar, which does not bring out the differential characters of all species; growth on this medium is much slower, but it has the virtue of postponing pleomorphic changes. Differential characteristics reappear on transfer to the maltose milieu d'epreuve.

Differential characteristics. Very many different kinds of dermatophytes have been described, some estimate as many as 200 or more, but many "new" species have been inadequately studied and often represent minor variants of established species. Primary differentiation into the three imperfect genera. Trichophyton, Epidermophyton, and Microsporum, is morphological and based on colonial morphology and the character of the macroconidium. A number of physiological studies have been carried out,81,181,219 and it has been found that certain species or strains are distinguished by requirements for vitamins or amino acids. These might provide a basis for identification, but so far at least, physiological characteristics have not been as useful for the differentiation of these forms as they often are for the characterization of bacteria.

Those characteristics established by the work of Georg⁸¹ and found to be useful are:

SPECIES REQUIREMENT

T. verrucosum	Inositol and usually thiamine
T. tonsurans	Thiamine
T. megninii	Histidine
T. equinum .	Nicotinic acid
T. violaceum	Thiamine

The test is carried out by planting the organism on deficient mediums.

While growing on the skin and its appendages, the thallus is differentiated only into hyphae and arthrospores; the latter, arising by fragmentation of the mycelium are to be regarded as oidia, as indicated earlier, though usually termed "spores" by dermatologists. The variety of differentiated structures, including aleuriospores (microconidia), and spindle spores or fuseaux (macroconidia), and vegetative structures, such as spirals, pectinate bodies, nodular organs, and racquet mycelium, appear on cultivation on artificial mediums. The differences are no doubt a consequence

of the nutritional state of the substrate and/or the semiparasitic existence on the host.

The first two genera listed above (the third does not invade hair) differ with respect to size and arrangement of the spores formed in the hairs. The genus Microsporum includes the small spore type (3 to 4 μ in diameter) and the genus Trichopyton, the large spore type (7 to 8 μ in diameter). This distinction is not absolute, for the very common species, Trichophyton mentagrophytes, forms small spores. Furthermore, the spores differ in arrangement. While the mycelium of Microsporum grows within the hairs, spores are formed only outside the hair and occur in irregular clusters in a kind of mosaic arrangement. The spores of Trichophyton, on the other hand, occur in chains inside or outside the hair.

Further differentiation of the organisms is made on the basis of location of the arthrospores with respect to the hair. The endothrix type (sometimes called black-dot ringworm) grows within the hair, and mycelium and chains of spores are found there. The hair often breaks off at the scalp line and gives an area of alopecia (usually cuboidal and accompanied by a kerion) and black dots of hair stubble. The ectothrix type forms spores only on the surface of the hair, though the mycelium grows inside. A third type is found in favus (T. schoenleinii) in which the organism grows in the hair but produces no

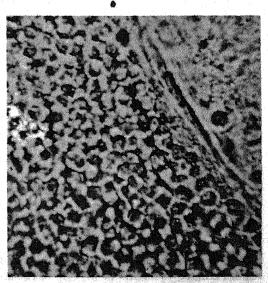

Figure 192. Endothrix tinea capitis (T, violaceum). Chains of spores within hair shaft, \times 100.

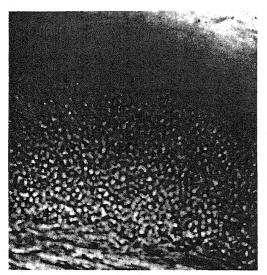

Figure 193. Ectothrix tinea capitis (*Microsporum audouinii*). Note the mycelium in hair shaft (lower left) with mosaic arrangement of arthrospores around hair shaft. × 400.

spores, only "air bubbles" in the hair shaft. The hair does not break off, but instead loses its color and luster and appears as a patch of gray hair.

It will be clear that differentiation of these genera may be approximated by, first, the clinical character of the disease and, second, by direct microscopic examination of epilated infected hairs, but identification is possible only by culture. In general, Trichophyton infections show a characteristic tendency to produce an inflammatory reaction with deep infiltration of the skin that is not usually produced by Microsporum infections; this difference is of some value in distinguishing between Microsporum infections and infections of the scalp with small-spore ectothrix Trichophyton. The animal strains of Microsporum such as Microsporum canis, however, also elicit inflammatory reactions. A severe inflammatory reaction with a raised mass of tissue, usually suppurating at many points, is called a kerion. Excessive fibrous scar tissue following an infection is called keloid formation.

Epidermophyton invades the superficial layers of the skin in tinea corporus and, in scales of the epidermis taken from the periphery of the lesion, the fungi are found as articulated filaments of mycelium breaking up into chains of round to oval arthrospores.

Pathogenicity. At present, the dermatophytes are known as parasites; they were once assumed to be obligate parasites either of man alone or of man and animals. The majority grow readily on laboratory mediums and also grow on such substrates as cereal grains, shed hair, horn debris, and sterilized fragments of straw in moist tubes and will remain viable in litter containing such materials for two to three years. If protected from dryness they may live on the wooden floors of shower rooms, dressing rooms, and dressing cabins, on mats, etc., for a considerable time. Furthermore. various dermatophytes have been isolated from soil and air,2 and it is probable that dermatophytes live a saprophytic existence, formerly unrecognized.

The dermatophytoses show, in many instances, a pronounced age and sex distribution, and there is some difference in the geographical distribution of the various species. Common ringworm or "gray patch" of *Microsporum audouini* of the scalp is confined to the young, occurring more often in boys than in girls, and it is rare after puberty. Others, such as the Epidermophyton species, occur for the most part in adult males. The distribution of intertriginous dermatophytosis of the feet, commonly known as "athlete's foot," in the young adult male is probably in large part an expression of risk. *M. canis* is more

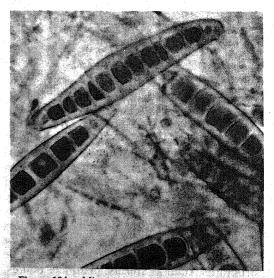

Figure 194. Microsporum canis macroconidia. The colony is fluffy white with a chrome-yellow reverse. Both micro- and macroconidia are found. Lactophenol-cotton blue; × 400.

common in this country than in Europe. except England, and the reverse is true of *T. schoenleinii*, while *T. concentricum* is well known in the tropics and certain parts of the Far East but is rare in temperate climates.

Some dermatophyte species appear to be so closely adapted to man that they are unable to infect lower animals; human infection is transmitted by contact.53, 151 These organisms are termed anthropophilic dermatophytes. Others not only produce infections in experimental animals, but animals such as the cat and dog are natural hosts, and human infection may be acquired from them. The reservoir of animaltype dermatophytes is of considerable epidemiological importance;78, 138, 158 survey showed, for example, that 37 per cent of cats and 22 per cent of dogs examined at random in this country were infected. Organisms such as Microsporum nanum⁶ are commonly found infecting pigs but not man. All these are referred to as zoophilic dermatophytes. Some are regularly contracted from the soil, such as Microsporum gypseum, and are termed geophilic.63,68

There is also a high degree of specificity as to the tissues attacked. While, as indicated earlier, these fungi are well adapted to parasitize the horny layer of the epidermis, they appear to be unable to invade and infect other organs of the body. The intravenous injection of Microsporum spores or emulsions of virulent *T. mentagrophytes* does not produce an infection of the internal organs of susceptible animals; rather, the microorganisms introduced tend to become localized in the skin and to develop where it is damaged as by scarification. However, it has been shown that dermatophytes, as well as several saprophytes, can be "trained" to assume a yeast-like phase similar to the deep-infecting fungi. In this transient condition the organisms can invade deep tissues of experimental animals.¹⁸⁴

Growth of the fungus in the skin and hair is more or less equal in all directions, and the lesions produced tend to have a circular form. For this reason the Greeks named the disease herpes, a term which still persists though modified as herpes tonsurans, herpes circinatus, or herpes desquamans to distinguish the dermatophytoses from herpetic infection of virus etiology. The Romans associated the lesions with lice and named the condition tinea, meaning any small insect larva. This name is likewise in common use. The English ringworm is, of course, a combination of the Greek and Roman terms.

The clinical conditions produced are termed: tinea pedis (athlete's foot); tinea corporis (ringworm of body); tinea capitis (ringworm of the scalp); tinea cruris (ringworm of the groin or "jock itch," also commonly caused by Candida); tinea ungium

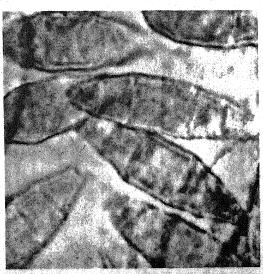

Figure 196. Microsporum gypseum (Nannizzia incurvata) macroconidia from the cinnamon-colored, powdery colony. Lactophenol-cotton blue; × 400.

Figure 197. Trichophyton mentagrophytes. Globose microconidia "en grappe" and spiral mycelium identify this fungus. The pencil-shaped macroconidia are identical to those of T. rubrum.

(ringworm of the nail or onychomycosis and commonly a Candida infection); and tinea imbricata (a special concentric ring form caused by Trichophyton concentricum).

With any species of dermatophyte, infection begins in the horny layer of the epidermis. Those which infect the hair follicles. hair, and nails soon invade these structures.

often producing little more than a scaling of the epidermis. Those which remain in the epidermis affect the drier parts of the skin. including the palmar and plantar surfaces, or the moister regions in the inguinocrural fold and the interdigital spaces. Thus a wide variety of clinical types may be observed. but the differences are more apparent than real, for the pathological changes are fundamentally the same in all types.

It was observed by Margarot and Devoze in 1925 that infected hairs and fungous cultures show fluorescence in ultraviolet This empirical observation has proved to be of very considerable practical value, especially in Microsporum ringworm of the scalp, although hairs infected with M. gypseum and M. fulvum often do not have this property. It is generally agreed that all hairs infected with Microsporum show a brilliant greenish fluorescence and those infected with T. schoenleinii a greenish but less brilliant fluorescence, both distinct from the bluish tint of normal skin. There appears to be some disagreement with respect to Trichophyton infection; it is reported by Davidson and Gregory³⁸ that in infections

^{*&}quot;Black light," commonly known as Wood's light because the radiation is filtered through Wood's nickel oxide glass, which holds back almost all the visible rays but passes the longer ultraviolet rays (peak at 3560 Å).

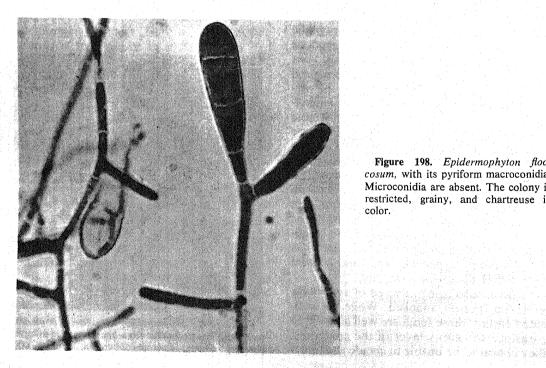

Figure 198. Epidermophyton floccosum, with its pyriform macroconidia. Microconidia are absent. The colony is restricted, grainy, and chartreuse in

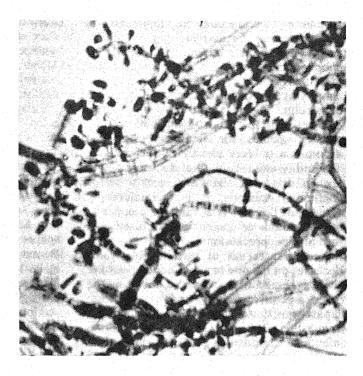

Figure 199. An unusual highly sporulating *Trichophyton rubrum*. Note the "teardrop" microconidia and elongate trichophyton type of macroconidia. The white fluffy colony has a wine-red reverse.

with some species the hairs fluoresce but in others they do not, while Lewis and Hopper¹⁴¹ state that all endothrix Trichophyton species show a dull bluish fluorescence of the infected hair, though hair infected with ectothrix Trichophyton does not fluoresce. It has been found that the fluorescence is due to the presence of a substance in the hair which can be extracted either with warm water after preliminary ether extraction or with dilute alkali. ¹⁸⁷ It is apparently not produced in culture, though some cultures (*T. tonsurans*) show some degree of fluorescence.

Immunity. Though an acquired immunity to infection has been demonstrated in experimental animals by a number of workers, the status of an effective immunity in man is uncertain. There have been some enthusiastic reports of the efficacy of vaccine therapy which are, perhaps, open to question. Much of the work that centers about local immunity appears to be uncritical; i.e., in many cases remarkable results have been reported but have not been regarded by immunologists generally as contributing materially to a solution of the general problem of local immunity. Hypersensitivity, however, is a common, though not invariable, manifestation of the immune response to dermatophyte infection, and desensitization procedures appear to have definite therapeutic value in certain cases. Normal serum appears to have some inhibitory effect on dermatophytes. 145

Hypersensitivity is manifested in two ways. One of these is the appearance of secondary, nonparasitic lesions on parts of the body remote from the infection. These are termed "ids," in a general sense mycid or dermatophytid, and more specifically microsporid, trichophytid, and epidermophytid. A similar condition, candidid, may result from a Candida infection. The mycid takes the form of a symmetrical eruption over relatively large areas, usually of the trunk, as a rash. The eruption may be vesicular with sterile content, papular, or lichenoid and is sometimes localized at the follicular pores. A rather frequent occurrence is a sterile vesicular eruption on the hands secondary to infection of the feet. It is generally believed that bits of mycelial debris from the lesion enter the blood stream and are eventually deposited in the skin, where they induce the local allergic response with destruction of the fungous elements. This view is based in part on a number of successful isolations of these fungi from the blood stream during the development of mycids. It is not known what part, if any, soluble substances liberated by the dissolution of the fungi play in the phenomenon.

Hypersensitivity may also be demon-

strated by the injection or application of preparations of dermatophyte cultures analogous to tuberculin and called trichophytin.36 The local and constitutional reactions that may be produced with trichophytin are much the same as those to tuberculin. The test does not differentiate between Microsporum and Trichophyton or their species, for all appear to contain a common or very closely related antigen. The utility and reliability of the trichophytin test in diagnosis form a subject arousing conflicting opinions. It is maintained by some that the test is a valuable adjunct to other methods of diagnosis when used with the proper precautions; others, however, regard the test as of questionable value because, on the one hand, infection does not always result in sensitization and, on the other, a positive reaction may only indicate a past infection unrelated to the condition in question. Persons with chronic T. rubrum infections frequently show an immediate wheal in response to trichophytin injection and essentially no delayed response. The relation of this to the chronicity of their disease is unknown but is interesting to speculate upon.

Laboratory diagnosis. As indicated earlier, classification of the dermatophytes is based largely on the clinical character of the infection, on colonial morphology on Sabouraud agar, and on minor difference in spore type. The differentiated structures developed in culture are, in some instances, of ancillary value. Fermentation reactions. emphasized by Castellani, are generally regarded as of little or no differential value. Animal inoculation is of minor importance unless the lesion is atypical and it is desirable to establish pathogenicity. Requirements for vitamins and amino acids and sexual mating are the only new tools to help in distinguishing species. These are of value in only a few cases. Laboratory diagnosis, then, is still a matter of looking at gross and microscopic morphology, an exercise in contemplative observation.

The specimen material must be chosen with some care and taken in abundance for both microscopic examination and culture. In ringworm of the scalp, epilated stumps of hairs may be taken and, in addition, scutula should be taken in favus and the contents of abscesses when the infection is suppurative. In infections of the smooth skin, scrapings from the scaly types should be taken

from the margins, rolling toward the normal skin, and the tops of vesicles may be clipped with small scissors in the vesicular types. Macerated epithelium may be taken from intertriginous infections, and nail scrapings and subungual hyperkeratotic masses from onychomycosis; the fungous elements are often more difficult to demonstrate microscopically in such specimens.

For direct microscopic examination the material is placed on a slide, a few drops of strong (20 to 40 per cent) potassium hydroxide solution added, the specimen covered with a coverglass, and the preparation heated slightly. Mycelial elements and spores may be found in such specimens. Permanent stained preparations may be made by mounting in Amann's medium, a lactic acid-glycerol-phenol solution containing cotton blue. As indicated earlier, sections may be stained by Gram's method or with methyl green-pyronine.

Sabouraud's agar containing cycloheximide (Actidione) 0.5 mg./cc. and Aureomycin 0.1 mg./cc. is the medium of choice for primary isolation as well as for determination of colonial character. A suitable substitute for Aureomycin is chloramphenicol or a penicillin and streptomycin combination. Inoculation should be relatively heavy and a number of plates prepared. Growth is relatively slow, usually 10 days to three weeks are required, and the dermatophytes grow well at 30° C.

THE PATHOGENIC YEASTS

The term, yeast or yeast-like, is the vernacular for a unicellular, nucleated organism which reproduces by budding. Such a definition is generally recognized as inadequate, in part because some yeasts reproduce by fission, in part because many produce mycelium or pseudomycelium under appropriate conditions, and in part because other fungi may exist in a unicellular yeastlike form which reproduces by budding, viz., the oidia described in the previous section. On the basis of sexual spore formation, some yeasts are ascomycetes, others are probably basidiomycetes (the ballistosporangenous yeasts), and still others have not been shown to have a sexual stage and are grouped with the Fungi Imperfecti. Clearly, then the term "yeast" is of somewhat uncertain significance; as commonly used, it refers to those organisms which exist usually or predominantly in a yeast-like form.

The yeasts belong in three fungal classes: the basidiospore-forming yeasts or Sporobolomycetaceae in the class Basidiomycetes, the ascospore-forming yeasts Endomycetaceae in the class Ascomycetes, and the asporogenous yeasts Cryptococcaceae in the Fungi Imperfecti. This last group contains the human pathogens. The industrial yeasts are, perhaps, the most familiar organisms. Saccharomyces cerevisiae, a member of the second group, is the common brewing yeast and occurs as two types: top yeasts are, perhaps the most familiar or of carbon dioxide and are found in the froth on the surface of the fermenting mixture, and the bottom yeasts, which sink to the bottom. Bread yeasts are usually top strains of S. cerevisiae. Another species of this genus. S. ellipsoideus, is the common wine yeast, occurring naturally on grapes and in the soil of vineyards, and its varieties are names for the various types of wine which they produce. These organisms are "perfect" yeasts, the cell body becoming an ascus during sexual union. Still other yeasts are lactosefermenters and are associated with the preparation of fermented milk beverages, such as kefir and koumiss, especially in southeastern Europe. Perhaps the commonest yeasts encountered as contamination in bacterial cultures and found growing on foods are the asporogenous *Rhodotorulae*; the pink or coral pigmented forms often observed are *Rhodotorula flava* or *R. glutinis*.

In view of the ubiquitous distribution of yeasts, not only in air, dust, and soil, but on the surface of the body and in the mouth, intestinal tract, and vagina, it is not surprising that these forms have been found in a variety of pathological processes. A great number of species have been described, most of them inadequately, in this connection. In many instances the yeast probably had no etiological relation to the disease, and in others the same yeast has been repeatedly described as a new species, thus giving rise to several synonymous names, and a very long list of "pathogenic" yeasts has accumulated.

Critical examination and consideration has now made it clear that only a very few species of yeasts are actually pathogenic for man and animals. The yeasts of medical importance produce a wide variety of diseases; these are listed in the accompanying outline with their basic differentiation and the classification generally accepted.

Classification of the Pathogenic Yeasts

Form-class: Deuteromycetes (Fungi Imperfecti) Form order: Pseudosaccharomycetales

Form-Family: Cryptococcaceae

Genus 1. Cryptococcus

Unicellular budding cells only, reproduce by blastospores pinched off the mother cell. Most are urease-positive. Cells surrounded by a capsule and starch-like substance produced. No carotenoid pigment.

Example: Cryptococcus neoformans (cryptococcal meningitis)

Genus 2. Torulopsis

Same as genus 1, but no capsule or starch-like polysaccharide produced.

Example: Torulopsis glabraeta (Torulopsis meningitis)

Genus 3. Pityrosporum

Mostly unicellular budding cells. Reproduction by blastospores that cut off from the mother cell by development of a cross-wall. Cell may adhere, forming short hyphal strands.

Example: Pityrosporum orbiculare (tinea versicolor)

Genus 4. Rhodotorula

Unicellular budding forms that may be encapsulated or produce pseudomycelium. Carotenoid pigments present.

Example: Rhodotorula mucilaginosa (rare pulmonary and systemic infections)

Genus 5. Candida

Reproduction by pinched blastospores; may form pseudomycelium or true mycelium. Ureasenegative usually. No capsules or carotenoid pigment.

Example: Candida albicans (candidiasis)

Genus 6. Trichosporon

Reproduction by blastospores and arthrospores. Mycelium and pseudomycelium formed.

Example: Trichosporon cutaneum (white piedra)

Genus 7. Geotrichum

Reproduction by arthrospore only. Forms a true mycelium. Some authors group this with Coccidioides immitis in the Arthrosporeae of Moniliaceae.

Example: Geotrichum candidum (rare pulmonary geotrichosis)

Candidiasis will be discussed in this section; the other pathogenic yeasts elsewhere.

CANDIDIASIS

"Monilia" is a nomen absurdum perpetrated in the nineteenth century. Unfortunately, the term is still used by clinicians and the public. Mycologically, the word Monilia refers to a black fungus growing on rotting wood, first described by Persoon. The correct term for the disease is candidiasis.

Candidiasis is one of the most frequently encountered of the fungous diseases. The organism Candida albicans, which is responsible for most infectious processes, is endogenous in man. It is part of the normal flora of the buccal cavity, large intestine, and probably the vagina. Under ordinary circumstances it is held in check by normal body defenses and other members of the normal flora. If this balance is changed as in debilitation of defenses, overdose of antibiotics, or local physiological change, the organism begins to proliferate at a rapid rate and establishes an infection. Not only is it ubiquitous, it is the most variable of of organisms in the clinical manifestations it may assume. Most commonly, it is associated with intertriginous dermatophytelike infection, as well as onychomycosis, tinea pedis, vaginitis, and thrush. It may also be involved in bronchitis, pneumonitis, and rarely meningitis and systemic involvement. 227

The organism displays a nutritionally governed type of dimorphism. Under favorable conditions of growth in the presence of fermentable carbohydrate, the organism grows as a budding yeast. 226, 234 In mediums without fermentable carbohydrate and with semi-anaerobic conditions and/or a high nitrogen content, the yeast elongates, forming pseudomycelium and mycelium accompanied by blastospore and chlamydospore production. When C. albicans is mixed with egg albumin or serum and incubated at 37° C., the yeast cells show "sprout" mycelium. This Reynolds-Braude phenomenon affords a rapid diagnostic procedure. 136 In tissue, elongation to form mycelium is commonly encountered. In experimental candidiasis, mycelium conversion occurred within two hours in the kidney after injection of C. albicans yeast. 120

The first description of a fungus of this

type occurring in disease was that of Langenbeck, who in 1839 found it in patches on the mucous membranes of the mouth and elsewhere at autopsy. Gruby (1842) confirmed this finding, and the organism was named *Oidium albicans* by Robin four years later. The generic name Candida has come to be commonly used, and the disease is termed candidiasis.

The causative organism. 236 In addition to the original Candida albicans, a considerable number of species of Candida have been described, including C. krusei, C. paropsilosis, C. tropicalis, and C. steallatoidea. The second most commonly encountered pathogen is C. tropicalis. It may be missed if the specimen is planted on a cycloheximide medium, as it is sensitive to this chemical. Together with C. albicans it is considered a pathogen. The other Candida are rarely isolated from disease processes. Some normal skin contaminants such as C. paropsilosis account for most Candida heart valve involvement. In fact, a large proportion of the current literature on these organisms is devoted to their differentiation, identification, and classification.²⁰⁶ Differentiation is made on the basis of various cultural characters, such as pellicle formation in liquid mediums, gelatin liquefaction, and the like, and differential fermentations. The last is the most practical laboratory method, but there is some disagreement as to the constancy of these characteristics. The R-B egg test described above is the most rapid method of identifying C. albicans.

These various strains are immunologically related and show marked cross-reactions. but the group is not homogeneous. A detailed antigenic analysis has shown the essential identity of C. albicans and C. tropicalis, and the separation of C. stellatoidea. Similar studies by Hasenclever and his associates 101, 102, 103 with C. albicans, for which chlamydospore production is the usual criterion for identification, showed that it is separable into two antigenic types, designated groups A and B. C. tropicalis falls into group A, C. steallatoidea into group B. Strains of C. tropicalis and C. steallatoidea, as well as C. albicans strains of both groups, are virulent for the mouse, 69 but the virulence of C. albicans for the rabbit appears to be significantly greater than that of the other species.

Pathogenicity. These fungi are commonly present in the mouth, vagina, and the intestinal tract in normal persons and

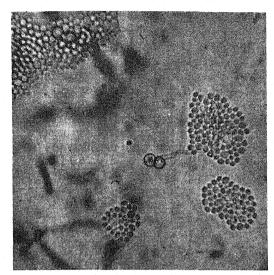

Figure 200. Live colony of Candida albicans which has produced a thick-walled chlamydospore on corn meal agar. (R. Murphy.)

are probably not highly virulent with respect to initiation of an infectious process. In fact, as in many of the mycoses, there is frequently a history of a debilitated condition or other predisposing factors. Several systemic conditions are known to favor Candida infection, principally diabetes mellitus. Others include vitamin deficiency (particularly of riboflavin and others of the B group), hypoparathyroidism, and lymphoblastomas, and overuse of broad-spectrum antibiotics. Candida infections have oc-

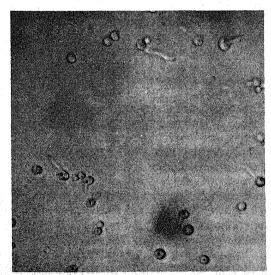

Figure 201. Sprout mycelium (R-B phenomenon) of *Candida albicans* after two hours in egg white at 37° C. × 400.

casionally heralded prediabetic diathesis and hypoparathyroidism before the disease was clinically apparent. In some instances in which they are associated with the development of a pathological process, there is some doubt as to their etiological role; in many others it is clearly evident that they are primary invaders and responsible etiological agents. Several workers, 134 particularly Louria and Brayton, 146 have demonstrated a humoral anti-Candida factor. Unlike an induced antibody, it remains at a particular level in normal individuals and is low or absent in diabetes, lymphoblastomas, and other diseases. Precipitating antibodies to soluble antigens of Candida are found in systemic disease.227

There is evidence that the treatment of other infections with the broad-spectrum antibiotics, especially the tetracyclines and chloramphenicol, increases the number of persons in whom Candida is found in the intestinal tract, vagina, and perianal infection, and it is related to the incidence of candidiasis which occurs as a sequel to prolonged therapy with these agents. While the suppression of susceptible microflora antagonistic to the fungi is probably concerned in the overgrowth of Candida, it has been suggested that such antibiotics may, in fact, enhance the virulence of these fungi or adversely affect the tissues concerned. There is a certain amount of experimental evidence supporting this. 20, 117, 118, 119 but its relative importance remains obscure.

Infections of the mucous membranes. Candidiasis of the mucous membranes is known as thrush and is one of the common mycoses. Intra-oral thrush, a superficial infection of the mucous membranes of the mouth, is the type most frequently observed and is considerably more common in nursing infants and children than in adults. In the past it has occurred in severe epidemic form in institutions such as foundling asvlums, but such epidemics are observed less often now. Thrush occurs more frequently in bottle-fed than in breast-fed babies, and the lesions not infrequently spread to the pharynx and even the esophagus. In adults, thrush generally occurs terminal to wasting diseases such as tuberculosis and cancer: dryness of the mouth associated with prolonged coma or near-coma appears to favor infection. It also occurs with some frequency as a mild vaginal infection in pregnant women which may or may not be associated with infection of the anus.

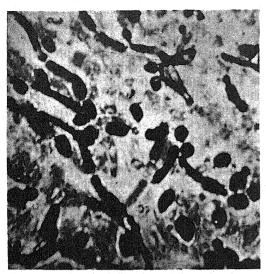

Figure 202. Candidiasis of kidney showing elongation of cells to form pseudomycelium and mycelium. Gram stain \times 600.

In the majority of cases the infection is mild and remains localized. Occasionally it may spread to other mucous membranes and to the skin, with the development of a generalized cutaneous eruption, intertriginous lesions, and Candida granuloma; such cases are sometimes fatal. In the cutaneous form in infants it is to be distinguished from infantile eczema and allergic hypersensitivities. The most common predisposing malady for cutaneous candidiasis is diabetes. Hematogenous spread with metastasis and abscess formation in the viscera has been observed.

The lesions appear as soft whitish patches, composed largely of fungous growth. They are readily removed and leave an eroded surface. There is some resemblance to a diphtheritic membrane, and lesions in the throat and on the tonsils have no doubt been mistaken for diphtheria. However, it is much easier to separate the membrane in candidiasis. On microscopic examination of the membranous material in wet preparation, the observation of a tangled mass of segmented mycelium admixed with budding yeast-like cells, desquamated epithelium, and leucocytes establishes the diagnosis. The fungus may be cultivated on Sabouraud's agar, but isolation in pure culture is more readily accomplished with cycloheximide agar. The isolated fungus must be differentiated from other yeasts.

Dermatocandidiasis. C. albicans is also causally associated with eczema-like lesions of the moist skin similar to those produced by E. floccosum. Infection of the folds between the fingers, erosio interdigitalis, is more common than dermatophytosis of this region, and is found most often in those whose hands are frequently wet. Perleche. an infection of the angles of the mouth, is another form of intertrigo produced by these fungi. Ill-fitting dentures may lead to local lesions under the plates. Candids, sterile vesicular or exudative lesions which appear on the hands secondary to a focus of infection elsewhere, are analogous to trichophytids and are a result of hypersensitivity.

The nails, chiefly of the fingers, are also attacked by C. albicans with the production of chronic paronychia. The condition is differentiated, clinically from onychomycosis by retention of the luster of the infected nail and the absence of vellowish discoloration, crumbling, and thickening of the soft tissues. The nail shows transverse ridges and eventually becomes thickened, distorted, and brownish in color, with frequent involvement of the surrounding nail bed (paronychia). Like interdigital infections, the infection is found most often in those whose hands are often wet.

On microscopic examination of nail and skin scrapings cleared in 10 per cent potassium hydroxide, hyphae may be present together with the budding yeast-like cells.

Bronchocandidiasis.31 There appears to be a distinct type of candidiasis of the respiratory tract which was first reported from Cevlon by Castellani. It has been observed in Europe and in this country but is apparently more common in the tropics; its frequency as a primary infection is uncertain. According to Castellani, two types of the disease occur: the mild form, chronic bronchitis characterized by dyspnea and cough, is afebrile, while the severe form is similar to tuberculosis and usually fatal.

The fungus may be demonstrated by direct microscopic examination and by culture, but such findings must be interpreted with caution,12 for the organism is frequently found in sputum in other diseases, especially tuberculosis. It is recommended that the throat be cleansed by gargling before the sputum is collected and that other contamination be avoided. Most strains are pathogenic for rabbits and mice, producing tubercle-like nodules within two or three weeks after inoculation.

THE SUBCUTANEOUS MYCOSES

Subcutaneous mycosis refers to a group of fungous diseases in which both the skin and subcutaneous tissue are involved but disseminiation to the internal organs does not occur or only rarely occurs. The etiological agents are classified among several unrelated genera. They have the following characteristics in common: (a) they are primarily soil saprophytes of very low grade virulence and invasive ability, and (b) in most human and animal infections they gain access as a result of traumatic implantation into the tissue. The list of organisms isolated from or designated as the cause of such conditions is long and varied.224 Bluegreen algae in monkeys and dogs, Protothecus zopfii (an algae) and celery blight (Cercospora apii) in man, and Beauvaria (a beetle fungus) in man and turtles are just a few of the interesting ones listed.84 This indicates that many, if not all, organisms have a potential to establish local infections under certain circumstances, depending on their adaptability and the response of the host.

Tissue response to these agents varies as to the etiological agent in question. In most cases the lesion tends to be localized, and the reactions that develop are similar to those elicited by a foreign body. Details of tissue response are discussed below.

The major disease types are: chromoblastomycosis, sporotrichosis, mycetoma (maduromycosis), and the recently described and relatively rare subcutaneous phycomycosis. Infection by agents of the three major groups is accompanied by a type of dimorphism. The organisms undergo a morphogenesis from their saprophytic form into a tissue or parasitic stage. In chromoblastomycosis and mycetoma the response seems to be to complex tissue factors and is called tissue dimorphism. Sporotrichum schenckii can be termed an example of thermal dimorphism. Mycetoma was discussed under the actinomycetes. The other organisms will be treated here.

CHROMOBLASTOMYCOSIS

Chromoblastomycosis was discovered by Pedroso in 1911, but his observations were not reported until 1920, the first case in the literature being reported from Boston by Medlar in 1915. The geographical distribution is wide, however, with the greatest number of cases being found in Puerto Rico and Brazil, and it is quite common in Costa Rica. Other cases have been observed in other parts of South America, Africa, and the Far East.²³ Present knowledge of the disease has been summarized by Carrión.²⁶

The causative fungus is closely related to the Hormodendrum-Cladosporium group of the Dematiaceae (Fungi Imperfecti) and was named Hormodendrum pedrosoi by Brumpt. Three types of sporulation are observed, the predominant type differing from one strain to another, and this has led to the splitting of strains into several genera with considerable confusion resulting. The new genus Fonsecaea was created by Negroni in 1936 and has gained some general acceptance, and the organism is, therefore, also commonly known as Fonsecaea pedrosoi. Since the Hormodendrum type of sporulation is not an outstanding characteristic. Carrión has proposed that the name F. pedrosoi be accepted as the only species and that four varieties, typicus, cladosporioides, phialophorica, and communis, be recognized on the basis of predominant type of sporulation. Presently four species are accepted.

ORE	TYPE	SPECI

- a. Cladosporium
 1. Phialophora verrucosa (c only)
 2. Cladosporium carrionii
 - 2. Cladosporium carrionii (a only)
- b. Acrothecia

 3. Fonsecuea pedrosoi (a, b, c). Spore is more elongate than compact; a, b and c sporulation is rare.
- c. Phialophora
 4. Fonsecaea compacta (a, b, c). Spores in chain are round and closely packed.

The (a) cladosporium type of sporulation is characterized by chains of acropetelously budding spores resembling Penicillium, the (b) acrothecia spore type has single conidia around the septa of the fertile mycelium, and the (c) phialophora type has a group of spores emerging from a phialid.

The organisms all have in common very slow growth of a gray to black-brown colony, lack of gelatin liquefaction, and identical tissue phase morphology. Mycelium is not formed in the tissues, and the parasitic phase of the fungus is a brown sclerotic cell which divides by central septation of the yeast-like cell. There is no budding. The granule, which is always brown, is easily seen in unstained material or in H and E stained tissue sections.

The disease is an infectious granuloma.

of the skin and subcutaneous tissues, occurring usually, though not always, on the feet and legs. It ordinarily begins with a small warty growth on the foot and extends upward through the development of satellite lesions. It almost always remains localized, metastases are very rare, and there are no constitutional symptoms. The disease develops very slowly; usually the case is of 10 to 15 years' duration at the time of examination, and some are known to have persisted for as long as 40 years. In advanced cases there is some elephantiasis of the affected limb, and great numbers of lesions. These vary somewhat and are of four general types: hard, elevated, pigmented nodules; large, cauliflower-like, prominent tumors; moderately elevated, dull red, scaly patches; and discrete or verrucous hyperkeratotic growths. The lesions are readily traumatized, and the disease may be complicated by secondary bacterial infection and ulceration. The sclerotic cells appear as spherical brown bodies, perhaps 12 μ in diameter, with a thick cell wall and granular protoplasm, and often show internal septation. They may be observed in biopsy specimens either within giant cells or free in the tissues, and are demonstrable in the epithelial debris obtained by scraping the lesions. The fungus may be cultured from such scrapings or from infected tissue. Chemotherapy is not satisfactory, iodide in large doses giving local improvement but not cure; excision

of the early papillomatous lesion is recommended. The use of amphotericin B and other agents has been reviewed by Procknow and Loosli.¹⁷⁵

There appears to be no evidence of spread of the infection from one person to another. Since the disease tends to occur on the legs and feet of barefoot outdoor laborers in the tropics, it seems probable that the fungi are saprophytes normally present in soil or decomposing organic matter (they have been isolated from lumber, where they cause "blueing"). When introduced into the skin by a splinter or thorn or through some minor abrasion, they may at times assume pathogenicity. There appears to be good evidence at present for lymphatic and hematogenous spread of the disease in rare cases. Involvement of the conjunctiva and central nervous system has been recorded, although there is some confusion in reported cases with cladosporiosis. F. pedrosoi has been isolated from the lungs in rare cases, and the possibility of a pulmonary portal of entry must be considered. Bacquero and others have been successful in preparing a skin test antigen which causes a reaction in infected patients.

SPOROTRICHOSIS (Sporotrichum schenckii)

Sporotrichosis was first recognized by Schenck in this country in 1898 and a few years later in France by Beurmann and Ramond. It has since been found all over

the world, though the majority of reported cases are from the United States, especially from the Mississippii and Missouri Valleys, and from Mexico and France. It occurs as an occupational disease in pottery workers in Cuba, and the source of infection is presumably the packing material.⁸⁸ The organism is favored by moderate temperature and high relative humidity. Epidemics have occurred due to the growth of the organism on timbers in mine shafts.

Fungi of the genus Sporotrichum are characterized by the production of pearshaped conidia directly from the mycelium which arise both laterally and at the tips of delicate sterigmata on a conidiophore. They are described as "palm tree-like." The characteristic arrangement is not apparent in smears from cultures, and the spores are usually found free, but the arrangement is readily demonstrable in slide cultures. The hyphae are considerably more slender. 2 μ in diameter, than those of most molds. The character of the growth on agar is different from that of other molds; the colony is first soft and creamy in consistency, becoming more firm as the culture grows older, and there is no cottony mass of aerial mycelium. The growth also becomes darker with age, being at first a light tan which deepens to a dark brown or even almost black. When cultured on blood cystine agar at 37° C.. it grows as a budding yeast and is quite as "yeast-like" as Blastomyces or Histoplasma. Mycelium is not formed in the tissues, and the parasitic phase of the fungus is a cigarshaped body resembling an elongated yeast cell, 1 to 3 μ in breadth and 2 to 10 μ in length. These bodies are found within the leucocytes and apparently reproduce by budding; they are rarely observed in human infections. They are not spores. Occasionally, so-called asteroid bodies, consisting of a central fungous cell with deep-staining tissue material radiating from it, are seen in human tissue sections and material from experimentally infected rat testes. Because the organism is seldom seen in tissue, diagnosis is dependent on growing the organism. Surgical excision is contraindicated, as it tends to spread the infection.

The organism described by Schenck was named Sporotrichum schenckii. That isolated in France was supposed to be a different species and came to be known as S. beurmanni. The differences between the two are in pigmentation (S. schenckii being the lighter), the formation of fewer lateral spores

by S. schenckii, and the fermentation of sucrose but not lactose by S. beurmanni and the reverse by S. schenckii. There also appear to be some differences in the clinical type of disease produced. These differences are not constant, however, being subject to environmental modification, and it is apparent that the two are but a single species, S. schenckii. The name S. beurmanni continues to persist in the literature, however, giving the impression of two recognized species. The fungus infecting horses, S. equi, is also identical with S. schenckii.

Pathogenicity for man. The most common form of sporotrichosis in this country is cutaneous; the primary lesion, appearing at the site of some minor injury, often on a finger, fails to heal, ulcerates, and is followed by the appearance of a series of subcutaneous abscesses along the course of the regional lymphatics. The subcutaneous lymph vessels can often be traced as reddened lines. In the series of cases reported by Gonzales Bonavides, the disease occurred on the hand in 37.5 per cent, on the forearm in 25 per cent, on the arm in 6 per cent, and on the leg in 9 per cent, with lymphangitis extension in 37.5 per cent. Infection seldom extends beyond the regional lymph nodes, and cases of generalized hematogenous infection are rare in this country, though apparently more common in France. Metastatic lesions may appear in the liver or lungs and are most common in the testicles. The firm nodules in the skin are suggestive of syphilitic gummata, and probably some cases of sporotrichosis have been so diagnosed. Ocular sporotrichosis also occurs but is quite uncommon.89 Pulmonary involvement has occurred.203

Epidemiology. Direct transmission the infection from man to man has been observed but is very rare. A certain number of human infections have also been contracted, either directly through bites or indirectly by contact, from naturally infected horses and rats. In the great majority of cases, however, the fungus is introduced into the tissues from plants through some abrasion. Thus in 14 of a series of 18 cases the infection followed wounds from barberry thorns. The disease has been observed in florists and the fungus isolated from sphagnum moss.76 It has been observed growing free on grains, and Benham and Kesten¹⁷ demonstrated its ability to grow on barberry and carnations; in the latter a bud rot was produced, an interesting example of infec-

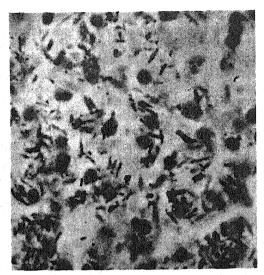

Figure 205. Sporotrichosis. Gram stain of heavily infected tissue showing elongate yeast-like cells.

tion of hosts as diverse as plants and man.¹¹⁵ It seems highly probable, therefore, that the fungus lives a saprophytic existence in nature, occasionally setting up an infection in man when mechanically introduced into the tissues.

Diagnosis. The diagnosis of sporotrichosis is established by demonstration of the fungus. The cigar-shaped parasitic cell is gram-positive, but may be found only rarely in gram-stained pus smears. These forms are relatively infrequent in human

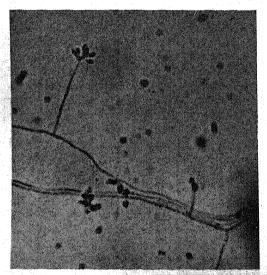

Figure 206. Sporotrichum schenckii mycelium with delicate conidiophore and conidia. Lactophenol-cotton blue; × 400.

material, and sporotrichosis is not excluded by failure to find them. The fungus is readily cultivated on Sabouraud's medium with cycloheximide from pus aspirated from unopened lesions. Rats are highly susceptible to infection, and inoculation of rat testes is of considerable diagnostic value. Injection of male rats intraperitoneally and intratesticularly with lesion material or culture results in a pronounced orchitis and generalized peritonitis with minute nodules on all peritoneal surfaces. The cigar-shaped cells are present in abundance in the rat lesion material and may be found readily in gram-stained smears.

Immunity. There is an immune response to infection manifested by the appearance of agglutinins (for spores), complement-fixing antibodies, and gel diffusion percipitins. They are of some diagnostic value, though the first two are somewhat nonspecific in that serums from persons with thrush or actinomycosis may give positive reactions. A cutaneous test with *sporotrichin*, a preparation analogous to tuberculin, is of similar specificity. A fluorescent antibody test has been used. 126

SUBCUTANEOUS PHYCOMYCOSIS

Since Lie-Kian-Joe and Emmons⁵¹ first described this entity in 1946, at least 100 more cases have been diagnosed24 and it may become a significant disease in tropical medicine. Unlike the other phycomycete diseases discussed in the following sections, there does not seem to be any underlying disease or predisposing factors apparent in the patients. The disease was first described in Indonesia but is now known in Uganda, Ghana, and India. In Africa it coincides with the geographic range of Burkitt's sarcoma; an insect vector has been postulated for both. The etiological agent was first designated Basidiobolus ranarum, a fungus associated with frogs and beetles but later shown by Greer⁹⁶ to be B. meristosporus. The disease is a long chronic process, often showing swelling of the arms, neck, chest, and trunk. The lesion involves the subcutaneous tissues and remains localized. Tissue section shows broad hyphae (20 μ) surrounded by an envelope of necrotizing eosinophilic debris. The lesion is a granuloma composed of chronic inflammatory infiltrate, foreign-body giant cells, fibroblasts, and thick-walled capillaries. Many

AND THE BOOK AND THE PROPERTY OF THE PARTY O

of the cases seem to have healed spontaneously or were lost to follow-up. Nothing is yet established as far as serology or treatment are concerned. Another member of the Entomophthorales, the spider parasite Entomophthora coronata, has been isolated from nasal polyps in horses and man.²²

THE SYSTEMIC MYCOSES

The systemic mycoses involve any or all of the internal organs of the body as well as cutaneous, subcutaneous, and skeletal systems. The usual portal of entry for the etiological agents involved is the lung, in contrast to the other mycoses. 95 Infections are extremely common, especially in the United States, but the vast majority of cases are inapparent. In asymptomatic disease the diagnosis is most often made through a number of tests. Sensitization, which reflects present or previous experience with the organism, is detected by means of skin test or other immunological procedure. Its occurrence may be revealed by the presence of healed lesions observed in roentgenographic examination or at autopsy after death due to other causes. If the infection is symptomatic, the clinical signs may be those of a mild, self-limited disease, or the infection may become progressive with severe symptoms, tissue damage, and frequently death.

The organisms involved often show a predilection for a particular organ or type of tissue. Histoplasma capsulatum is an intracellular parasite of the reticulo-endothelial system; Cryptococcus neoformans prefers the central nervous system, Blastomyces dermatitidis usually involves cutaneous and mucocutaneous tissue. On the other hand, any one of the organisms can elicit the same type of symptomatology and tissue response and can mimic many other systemic or cutaneous diseases.

The diseases will be discussed in three sections: thermal and tissue dimorphic fungi, cryptococcosis and related fungi, and the rare mycoses.

THE DIMORPHIC SYSTEMIC FUNGI

One of the most remarkable and interesting phenomena exhibited by the fungi that infect man is dimorphism. The organisms involved exist in a saprophytic or mycelial phase in nature but undergo a morphogenesis to a parasitic stage during the process of infection. The change is apparently an adaptation to an unfavorable environment and to a degree is inherent in most all fungi. Several harmless saprophytes and dermato-

Thermal Dimorphic Fungi

DISEASE AND ORGANISM	saprophytic phase (25° C.)	parasitic phase (37° C.)
Histoplasmosis Histoplasma capsulatum	Septate mycelium, microconidia tuberculate chlamydospores. Colonies white-beige and fluffy.	Budding small yeast 1 to 5 μ Large yeast (5 to 12 μ) in African histoplasmosis H . duboisii
North American blastomycosis Blastomyces dermatitidis	Septate mycelium, microconidia pyriform, globose, or double. Colonies white-buff and fluffy or glabrous.	Thick refractile wall, budding yeast 8 to 20 μ . Broad-based bud
South American blastomycosis Blastomyces brasiliensis	Similar to B. dermatitidis.	Large, multiple, budding yeast cells 20 to 60 μ .
Sporotrichosis Sporotrichum schenckii	Pyriform conidia on delicate conidio- phores. Delicate septate hyphae. Colonies verrucous white with black underside.	Fusiform, oval, budding cells in culture 5 to 8 μ . Asteroid, cigar-shaped bodies only in tissue
Keloid blastomycosis Loboa loboi	Not known in culture.	Single, budding yeast, usually remain attached in long strands 8 μ . Exaggerated granulomatous and keloid response.

Tissue Dimorphic Fungi

DISEASE AND ORGANISM	SAPROPHYTIC PHASE	PARASITIC PHASE
Coccidioidomycosis Coccidioides immitis	Branched, vegetative mycelium which fragments into barrel-shaped arthrospores. Colonies moist and wooly, "moth eaten."	Spherules 10 to 80 μ with endospores.
Rhinosporidiosis Rhinosporidium seeberi	Not known in culture.	Spherules 100 to 300 μ with endospores.
Adiospiromycosis Emmonsia parva and var. crescens	Dense, dry, flatish, tan colony, aleuriospores on pedicits, 3 to 4 μ .	Spherules 40 μ (E. porva), 500 μ (var. crescens) also induced at high temperature (40° C). No endospores.

phytes have been induced into a transient yeast-like stage in which they are invasive for deep organs of experimental animals. 180, 184 The organisms well known as agents of systemic disease are generally unrelated species that seem to share an exaggerated ability to adapt to mammalian tissue. Infection, as far as the organism is concerned, is essentially a blind alley, as it is usually of no benefit in disseminating the species. The soil form produces the infectious spores, man-to-man transmission is essentially unknown, and the organism usually dies with its host.

The factors that have been cited as important in bringing about the transformation of the saprophytic to the parasitic stage are many. 167 Among others, combinations of temperature, carbon dioxide tension, reduced oxidation-reduction potentials, free sulfhydral groups, and liquid mediums have been described as necessary. 144, 190, 196 In several organisms transformation is produced in tissue or a simulated environment not necessarily related to temperature. The organisms seem to fall into three categories: the thermal dimorphic fungi, the tissue dimorphic fungi, and nutritional dimorphism (see section on Candida). In thermal dimorphic fungi, morphogenesis is to a budding yeast-like (Y) stage from an elargate saprophytic mycelial (M) phase. There may be ancillary factors necessary, as already mentioned, but yeast stage growth in vitro and in vivo is governed by temperature. This has been shown by injecting poikilothermic animals with the organisms (either growth phase). In animals incubated at 25° C. infection occurred with mycelium in the tissues; if they were incubated at 37° C. infection was accompanied by trans-

formation to yeast stage growth.197 It has been speculated that a temperature-sensitive enzymatic pathway is involved. In tissue dimorphic fungi, the associated parasitic stage is not a budding yeast but assumes a variety of forms, including a spherule in coccidioidomycosis and adiospiromycosis; a planate dividing round cell in chromoblastomycosis, and a distorted mycelial ball in mycetoma. Injection of frogs with Fonsecaea pedrosoi causes infection with associated granule formation at 25° C.¹¹¹ and, similarly, lizards and frogs infected with Coccidioides immitis produced spherules at room temperature.111 The thermal dimorphic fungi are a well-delineated group and are described in the first of the two accompanying tables. The tissue dimorphic fungi are less well defined and are described in the second table. The tissue dimorphic fungi also include the organisms of chromoblastomycosis and mycotic mycetoma previously discussed. Most of these diseases are treated with amphotericin B.50, 175, 222

NORTH AMERICAN BLASTOMYCOSIS

The fungous disease known as North American blastomycosis was first observed in Baltimore in 1894 by Gilchrist and is sometimes called Gilchrist's disease. The great majority of cases have been found in this country,216 concentrated in the north central and eastern states,202 hence the name American blastomycosis. The disease has been observed often in the state of Illinois and is occasionally called Chicago disease. At least five cases have been reported and substantiated from Africa, which considerably extends its endemic range.⁵² Analysis of presumptive and inadequately described cases is difficult because of the usual failure to distinguish this disease from European blastomycosis (cryptococcosis), or African histoplasmosis (large yeast *H. duboisii*). *B. dermatitidis* may also exist in a small yeast form, which is difficult to differentiate in tissue from the histoplasmosis organism.

The causative organism. This fungus was isolated in 1896 by Gilchrist and Stokes from a second case of the disease and named Blastomyces dermatitidis. It is dimorphic. occurring only as a unicellular, budding, yeast-like form in the tissues, but as a mycelial form in culture. The unicellular form may be observed in potassium hydroxide preparations of pus or sputum. The cells are large, 8 to 10 μ in diameter, round or oval, doubly contoured, and multinucleate. and they show a single broad-based bud. The granular content of the cells distinguishes them from air bubbles or fat droplets, and identification is practically certain if budding cells are found. The perfect stage has recently been described Ajellomyces dermatitidis and is in the family Gymnoascaceae. The organism is, therefore, closely related to the dermatophytes.

Colonial morphology. This unicellular morphology also occurs in cultures on blood agar, microscopic examination showing budding cells with a few rudimentary hyphae. The colony developing at 37° C. is wrinkled and waxy and somewhat similar in appearance to those of the tubercle bacillus. In culture on Sabouraud's agar at 25° C.

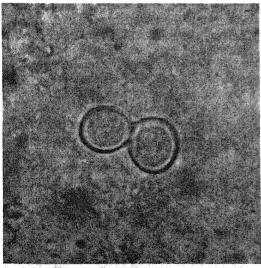

Figure 207. Potassium hydroxide preparation of pus showing yeast phase of *Blastomyces dermatitidis*. Note the broad-based bud and thick wall. × 400.

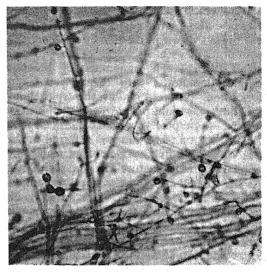

Figure 208. Mycelial phase of *Blastomyces dermatitidis*. Chrysosporum type of conidia. Lactophenolcotton blue: × 400.

the mycelial form appears. The colonial morphology is somewhat variable, and three types are distinguished. The "mealy" type is most often observed in primary isolation cultures and is similar to the growth on blood agar; microscopically the fungus is transitional between the unicellular and mycelial forms, with many of the cells tending to form articulated chains. After one or two transfers, the growth may assume a prickly surface, the prickles or spicules consisting of closely packed mycelial filaments which tend to become loose and cottony with continued incubation. The third type, sometimes observed on primary isolation and commonly found on laboratory cultures which are frequently transferred, is characterized by a white colony growth with abundant aerial mycelium; in these colonies the unicellular form has completely disappeared and growth consists of septate hyphae. Conidia are borne on lateral conidiophores. The mycelial form reverts to the unicellular type in experimental infections or when cultivated on practically any medium at 37° C. An odd metabolic product of its metabolism is ethylene.

Pathogenicity for man.²⁰¹ There are three types of disease processes: (a) primary cutaneous, (b) primary pulmonary, and (c) systemic, which may result from either of the former. Most infections are acquired through the pulmonary route. The primary skin lesion begins as a small firm papule

about which secondary nodules develop which enlarge with coalescence. The process breaks down in the center and becomes suppurative, with discharge of pus through small fistulas. The inflammatory reaction is granulomatous, with connective tissue formation, proliferation of the epithelium, mononuclear infiltration (pseudoepitheliomatous hyperplasia), and sometimes giant cell formation. The fungus is found in the pus of minute miliary abscesses which are a characteristic feature of the pathology. As the disease progresses, therefore, a large elevated mass of tissue, with an irregular ulcerated surface, is formed and oozes pus from multiple small openings upon pressure. The resemblance to epithelioma or tuberculous ulcer is sometimes striking. Lesions with pronounced epithelial proliferation simulate tuberculosis verrucosa. The process spreads slowly through the subcutaneous tissues and often becomes generalized by way of the blood stream. There is healing in the center of the lesions with scar formation. Biopsy for histological or cultural examination should be taken from the active edge of the lesion.

Primary infection of the lungs often closely resembles tuberculosis or histoplasmosis clinically, with cough, pain in the chest, weakness, sometimes hemoptysis, and productive sputum late in the disease. The pathological picture is variable in that there may be focal or diffuse consolidation, and the abscesses may be miliary or there may be larger nodules. Cavitation occurs but is limited to small areas. The microscopic picture also resembles tuberculosis, and sometimes it is difficult to differentiate unless the budding cells are found.

With generalization from primary foci of infection, multiple small abscesses of hematogenous origin occur throughout the body. They are most common in the subcutaneous tissues and differ from the primary skin lesions in that they develop without pain or marked erythema, are soft, and evacuate considerable quantities of pus when opened. In contrast to the primary skin lesions, which most commonly occur on exposed parts of the body, the secondary subcutaneous abscesses are usually found in covered areas. Secondary abscesses also commonly develop in the viscera, in muscles, under the periosteum, and especially in the prostate. The eye may rarely be affected.62 The disease may be chronic and persist for years, but in the generalized infection there is a septic febrile reaction and the case fatality rate is high. The diamidines, stilbamidine and 2-hydroxystilbamidine, have therapeutic activity¹⁷⁵ but relapses are not uncommon. More recently, amphotericin B has given very promising results.⁹⁹ Saramycin (X5079C) is now being tested.

The source of infection is not clear. Very often the primary skin lesion develops from a wound infection, and a large proportion of the cases have been in farmers. There is reason to believe that in most cases pulmonary infection is primary, presumably acquired by inhalation, and in some cases there are no other lesions, or cutaneous lesions may be overtly primary but secondary to the lung infection. Males are much more frequently attacked, and the incidence is higher in the 20- to 50-year-old group. The fungus has been recovered from soil⁴⁰ but very rarely in contrast to other pathogenic fungi. The yeast cells of the organism tend to lyse when placed in soil. The reason for this is as yet unknown. 154

Unlike other systemic mycoses, infection with *B. dermatitidis* is a progressive disease; spontaneous remission is uncommon.

Pathogenicity for lower animals. The inoculation of experimental animals is not uniformly successful and has no diagnostic utility. Mice are more susceptible than guinea pigs, and rabbits are almost completely resistant. Small caseous nodules develop on the peritoneal surfaces of intraperitoneally inoculated animals, and the type of tissue reaction varies with the resistance of the animal and the virulence of the strain of fungus from frank abscess formation to tubercle-like lesions. An instance of canine infection apparently transmitted to man has been reported.

Immunity. There appears to be little or no effective immunity in man to the spread of the infection since generalization is common. Complement-flxing antibodies are produced, however, and the titer is related to the severity of the infection. 64, 65 Long persisting titers are generally considered a sign of poor prognosis. Hypersensitivity to the cell substance of the fungus occurs also and is manifested as a delayed tuberculin-like response to intradermal inoculation of suspensions of killed cells. 152 Unfortunately, there is a cross-reaction with histoplasmosis

(or histoplasmin) and to a lesser extent coccidioidomycosis (or coccidioidin). The hypersensitivity is of practical importance in that it contraindicates the therapeutic use of iodides; desensitization may be accomplished with vaccine. It has not as yet been possible to demonstrate an effective immunity to the experimental infection in laboratory animals. Other serological procedures useful in diagnosis and prognosis are the gel diffusion test and fluorescent antibody procedure.

Diagnosis. As indicated above, the yeastlike unicellular form of the fungus can be demonstrated by direct microscopic examination of pus or sputum mounted in potassium hydroxide. Positive complement-fixation and skin tests are of value in pulmonary and systemic infections. An unequivocal diagnosis can be established, however, only by isolation and identification of B. dermatitidis. This is usually not difficult, as the fungus grows readily on cycloheximide bloodagar at room temperature. After growth has been established, it is necessary to confirm the diagnosis by showing the dimorphism to the yeast stage. This is done by taking mycelium from the cycloheximide bloodagar plate and planting on plain blood agar and incubating for several weeks at 37° C. The yeast stage of Blastomyces and Histoplasma are sensitive to cycloheximide. 153

COCCIDIOIDOMYCOSIS⁶¹

Coccidioidomycosis, coccidiomycosis, or coccidioidal granuloma was first observed in Argentina in 1892 by Posados and by Wernicke; two years later it was described independently in California by Rixford. The causative organism was thought to be a protozoan and named Coccidioides immitis. It resembled the coccidia group of protozoan parasites, a group that includes Eimeria coccidiosis of chickens and such other bird pathogens as Isospora. Ophuls and Moffitt showed by culture that it is a fungus, but this does not invalidate the name. Its relationship to other fungi is uncertain. Because it is more or less nonseptate in its early growth and there is resemblance of spherule production to sporangia formation, it was long considered an imperfect phycomycete. Some authors place it along with Geotrichum in the tribe Arthrosporeae of the Moniliaceae (Fungi Imperfecti).235 This evades the issue but will suffice until true relationships are discerned. Though originally reported from South America, the disease appears to be uncommon and is most prevalent in the San Joaquin Valley in California and in the dry regions of the southwestern United States and north central Mexico. There are scattered reports from Central America and South America. The organism is associated with a particular ecologic niche known as the Lower Sonoran life zone. Reports of rare cases in other parts of the world are probably the result of transmission by fomites. A coccidioides-like disease is recognized in Russia, the etiology of which is not yet well described.

The causative organism: parasitic stage. This fungus differs markedly from the yeastlike fungi in that it never reproduces by budding, and it differs from most other pathogenic fungi in that it reproduces within the tissues exclusively by a process of endogenous spore formation. The newly liberated spores are small mononucleate spheres 1 to 3 μ in diameter and appear as a central, deeply stained mass of protoplasm surrounded by a double-contoured cell wall. The cell enlarges, soon becoming multinucleate, and eventually reaches a diameter of 50 to 60 μ . A central vacuole appears early and in later stages occupies a large portion of the cell, the protoplasm appearing as a thin peripheral layer. The peripheral pro-

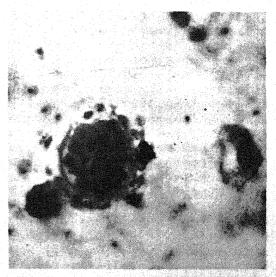

Figure 209. Breaking spherule of *Coccidioides* immitis in liver tissue with endospores. Gridley periodic acid-Schiff hematoxylin; \times 400.

toplasm becomes vacuolated by cleavage planes and an indefinite number of multinucleate protospores become delimited by the formation of cell walls; the protospores in turn subdivide to form spores and the entire cell assumes a function similar to that of a sporangium. With rupture of the cell wall the mature spores are liberated, and the developmental cycle begins again.137 It is at rupture time that neutrophils invade the area and the antigen released induces effective immunity. The effective antibody seems to be directed against newly released endospores. The same type of spherule-endospore cycle occurs in rhinosporidiosis. Spherules are also found in adiospiromycosis. All of these forms may be observed in the tissues and in pus, though recently disseminated spores are difficult to demonstrate. Hyphal forms have been observed in the tissues but are very rare. The morphological phase found in the tissues is determined by various environmental factors.33

The causative organism: saprophytic stage. The fungus will grow on a variety of sugar-containing mediums, but Sabouraud's agar is the medium of choice. It grows best at 37° C. under aerobic conditions. On artificial culture mediums the growth is that of a mold. The colony may be smooth and waxy when young, aerial mycelium is soon formed, and it becomes gray or brownish in color. Fragmentation with the formation of artho-

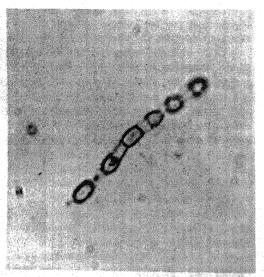

Figure 210. Mycelial phase of C. immitis. Barrelshaped arthrospores with empty cells in between. Lactophenol-cotton blue; × 400.

spores begins on side branches which are double-sized distally. The arthrospores are barrel-or cask-shaped, are thick-walled, and have an empty space between successive spores.

Pathogenicity for man.²¹⁴ For many years infection with C. immitis was known only as coccidioidal granuloma, a severe disease in which the case fatality rate was thought to be 90 per cent or more. Infection with this fungus is, however, much more prevalent and less severe than had been supposed. It is estimated that 10 million people in the southwestern United States have or have had coccidioidomycosis. Healed lesions of coccidioidal granuloma are found at autopsy of persons dying of other causes, and similar arrested lesions have been produced in white rats. Furthermore, it was shown by Dickson in 1937 that the disease may take a second form (known as "valley fever" or "desert rheumatism"), a benign, acute, self-limited respiratory infection, in addition to the chronic, progressive granulomatous disease. He suggested that these be designated primary and secondary or progressive coccidioidomycosis respectively, and these terms are now coming into general use. It is now felt that the experience of the benign self-limited disease confers a rather effective immunity. Coccidioidomycosis is the most virulent and most dangerous of all the fungous diseases. Many laboratory accidents have occurred. sometimes fatal. Though the dissemination rate is less than or near 1 per cent, it may be 10 times that in dark-skinned individuals. Any extension beyond the benign selflimited disease must be considered very dangerous for the patient and treated as such. In South America the infection is known as Posada's disease.

Primary coccidioidomycosis. The infection is acquired by inhalation of the spores, and the disease varies in severity in recognized cases from that of a common cold to that of cases resembling influenza with pneumonia, cavitation, and high fever. In a small proportion of the cases, possibly 5 per cent, an exanthem-like erythema nodosum or erythema multiforme occurs, and the disease is recognized as "the bumps," desert rheumatism, valley fever, San Joaquin fever, etc. Persons showing this allergic response very rarely develop serious progressive disease. Many infections are symptomless, however. In a group of 1351 cases

studied by Smith et al., 60 per cent were symptomless, and dissemination with development of the progressive disease occurred in about 1 per cent of the clinically apparent infections. They also noted that dissemination occurred 10 times as frequently in the Negro, Mexican, Portuguese, or Indian as in the white. 116 Minor "epidemics" may occur such as that described by Davis, Smith, and Smith³⁹ in which seven of 14 persons who spent two days on a desert field trip near the San Joaquin Valley became infected, and Goldstein and Louie reported that, of several thousand soliders exposed during military training in an endemic desert area, 75 contracted the disease. All but one made rapid progress to complete recovery, but the remaining individual developed a generalized infection and coccidioidal granuloma. A similar incident occurred in a prisoner-of-war camp near Florence, Arizona, and in a housing development called Paradise Valley near Phoenix. Arizona. The disease is also a major problem in northern Mexico. Spontaneous recovery is the rule, and only rarely does the disease progress to the secondary type. Residual pulmonary lesions, closely resembling healed tuberculous lesions, are common.¹⁰⁵ They differ from healed histoplasmomas or tuberculomas in that they rarely calcify.

Secondary or progressive coccidioidomycosis.211 The progressive type of infection results in cutaneous, subcutaneous, visceral, osseous, and central nervous system lesions, as well as extension of lesions into the lungs. If the disease is well established in the lung, it rarely remains exclusively pulmonary. The cutaneous type closely resembles blastomycosis but is a much more severe disease, with fever and a greater tendency to hematogenous spread. Elsewhere the lesions closely resemble those of tuberculosis, and, in fact, differentiation from that disease may often be possible only by demonstration of the fungus. Meningeal involvement is nearly always fatal. It is not known whether the progressive type of disease results from a new infection or reactivation of arrested primary lesions, probably the former. Amphotericin B is reported to be an effective chemotherapeutic agent in the disseminated infection, 32, 213 but a more effective drug is greatly needed. As in the treatment of all systemic fungous diseases, the toxicity, especially the nephrotoxicity, is a major side effect. Other side effects are fever, anemia, phlebitis, and various allergic responses.

Pathogenicity for lower animals. The disease occurs naturally in domestic animals including cattle. 150 sheep, and dogs and also in certain wild rodents in endemic areas. The latter include three species of pocket mice. Perognathus baileyi, P. penicillatus, and P. intermedius: the kangaroo rat, Dipodomys merriani; and the grasshopper mouse, Onychomys torridus. The disease can be disseminated to a new area from the carcass of an animal that has died from it. Experimental animals are readily infected; both rabbits and guinea pigs are susceptible to intraperitoneal inoculation and mice to intracerebral inoculation. Mice, inoculated intracerebrally 66, 127 or intraperitoneally, are used for virulence assay.

Immunity. Since it is now apparent that infection with *C. immitis* can take a mild form from which spontaneous recovery is the rule, that arrested lesions occur with some frequency, and that the case fatality rates in the severe progressive type of disease are not as high as once thought, it is indicated that there is, on the one hand, an appreciable natural resistance to infection and, on the other, an effective immune response.

The immune response is manifested in part as the development of a hypersensitivity to the parasite. Coccidioidin¹⁷⁷ is, like tuberculin (OT), prepared from liquid cultures of the parasite, but there is some difficulty in reproducing potencies. An immunologically active polysaccharide appears to make up at least a part of the active principle, producing both skin reactions and precipitin reaction. Coccidioidin is inoculated intradermally, a positive reaction appearing in 24 to 48 hours. The hypersensitivity appears in a few days to a few weeks after infection, recent infections and severe infections resulting in stronger reactions than old infections and mild infections respectively. The test appears to be highly specific, though there is as yet some disagreement as to its interpretation.

Humoral antibodies are formed also, and complement-fixation^{169, 212} and precipitin tests, using an autolysate of culture as the antigen, have been developed and are specific. In general, serum antibody is not detectable prior to the development of skin sensitivity. Precipitin appears first and is demonstrable in 50 per cent of cases by the

end of the first week of the disease and in 90 per cent or more by the third week, and then gradually falls until no titer is demonstrable after seven months. The complement-fixation reaction becomes positive more slowly, with about 8 per cent positive reactions by the end of the first week, and reversion becomes apparent by the second month. In general, then, precipitating antibody characterizes the primary stage of the disease with about 78 per cent positive reactions as compared with 55 per cent positive complementfixation reactions, while complement-fixing antibody occurs in the secondary or progressive stage in 98 per cent of cases in contrast with 36 per cent positive precipitin reactions. Thus the titer of complementfixing antibody has considerable prognostic significance; rising titer is indicative of the development of the progressive granulomatous form of the disease, often before this is evident clinically.212 Vaccines of various types have been developed and tested, but their efficacy is yet to be determined. Gel diffusion and fluorescent antibody techniques also have been developed. 125

Diagnosis. The laboratory diagnosis of coccidioidomycosis is dependent upon the demonstration of the parasite, the diagnostic value of a positive coccidioidin reaction being somewhat uncertain. As indicated earlier, it may be found on direct microscopic examination of pus, spinal fluid, and tissues but may be difficult to demonstrate in the sputum. Lactophenol-cotton blue or Mallory's eosin and methylene blue may be used for staining. Though C. immitis grows without difficulty on sugar-containing mediums, it has been cultured in a surprisingly small proportion of cases. It grows on cycloheximide medium. There is a very considerable hazard in culturing the fungus owing to the infectivity of the spores, and special precautions are required.⁷

Epidemiology. In the endemic areas of the southwestern United States, the proportion of reactors to the coccidioidin test is high, ranging from 46 to 90 per cent. The prevalence of infection in these regions appears, therefore, to be much higher than suspected earlier. A very large proportion of these reactors have no history of coccidioidomycosis.²¹⁴ It has been estimated that only 5 per cent of infected persons show sufficiently pronounced clinical symptoms to be detected and diagnosed.

a that had in the

Though, as indicated earlier, the disease occurs in domestic animals and certain wild rodents, there is no evidence of direct transmission of the infection from animals to man, although dead animals may contaminate the soil in which they are buried. It seems likely that both man and animals are infected by the inhalation of spores contained in dust; there is frequently a history of exposure to dust storms in human cases, and the fungus has been isolated directly from dust. *C. immitis* is a saprophyte which infects animals and man by chance; the reservoir of infection appears to be in the soil.^{39, 43, 140}

RHINOSPORIDIOSIS

Rhinosporidium seeberi is the name given to the agent of a chronic granulomatous disease characterized by production of polyps or other manifestations of hyperplasia on mucous membrane surfaces. The disease is characterized by friable, highly vascular, sessile or pedunculated polyps which may appear on almost any mucosal surface. The nose, nasopharynx, or soft palate is most often involved. The conjunctiva and lacrimal sac are also commonly involved. Lesions

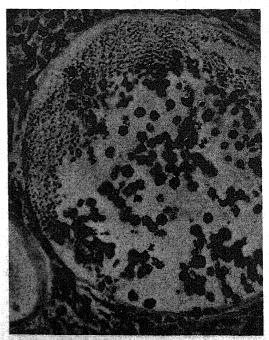

Figure 211. Giant spherule of Rhinosporidiosis in nasal polyp. Hematoxylin and eosin; × 400.

MANUFACTURE STATE

have been found on larynx, penis, vagina, rectum, and skin. The disease was first reported in 1896 by Seeber in South America. At least 200 cases are now known in Brazil. over 1000 in India and Ceylon; very rarely are cases reported in other parts of the world. Histologically, a typical tumor is composed of squamous or columnar epithelium showing a stroma of connective tissue, capillaries, and fungal spherules. The spherules are 10 to 200 μ in diameter and may contain 16,000 to 20,000 endospores. The cycle of development is similar to that in coccidioidomycosis. The organism has never been cultured. Some authors describe a protozoan-like karyosome along with a nucleus, and perhaps the disease, like Pneumocystis carinii infection, is an obscure protozoanrelated disease. The organism seems to be associated with stagnant water and may be a natural parasite of fish or other aquatic life.

ADIOSPIROMYCOSIS

This is a pulmonary disease found in many species of rodents throughout the world. It has rarely been described in man. The spores (2 to 4 μ) of the soil fungus are inhaled into the lungs, where they enlarge to a huge spherule. Development stops at this point and no endospores or buds are produced. The name adiospores refers to the enlargement and arrest of a fungal spore.

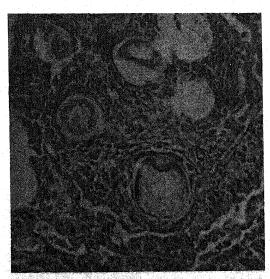

Figure 212. Adiospiromycosis spherules in the rat lung. Note the absence of endospores.

There is little host reaction. Adiospores can be produced in vitro by incubation at 40° C.⁴⁷ The fungi involved were described as two species by Emmons and named Emmonsia parva (Haplosporangium) and E. crescens. E. parva produces spherules up to 40μ ; E. crescens up to 500μ . Otherwise there is no difference in them. The organism is a soil saprophyte and grows on medium as a fluffy white colony producing single small (3 to 7μ) conidia on a conidiophore. Some authors classify them with Blastomyces dermatitidis in the genus Chrysosporium.

PARACOCCIDIOIDOMYCOSIS

The disease known as paracoccidioidal granuloma, Lutz's disease, or South American blastomycosis occurs in Brazil and elsewhere in South America and in Africa¹⁹³ but has not yet been observed in this country. The causative organism is Paracoccidioides brasiliensis which, despite its name, is not closely related to C. immitis but may be related to B. dermatitidis; it is also known as Blastomyces brasiliensis. It is a veast-like fungus, proliferating by budding in the tissues, and grows in a compact cerebriform colony on Sabouraud's agar, eventually producing a white aerial mycelium and single or double conidia shaped similar to those of B. dermatitidis.

The disease is clinically similar to coccidioidomycosis and blastomycosis.147 The fungus enters the body via the mouth to produce ulcerative granulomatous lesions which spread to the tongue, lips, and nose. The infection spreads via the lymphatics to produce lesions of the viscera and, often, pulmonary involvement. It is often fatal. It may also be acquired by inhalation, but rarely. Guinea pigs are usually infected by intratesticular inoculation and may also be infected by intratracheal inoculation. The fungus will grow readily on the chorioallantoic membrane of the embryonated hen's egg. There is a fluorescent antibody diagnostic technique described.205

Diagnosis is established by microscopic demonstration of the multiple budding cells (in contrast to the singly budding cells of B. dermatitidis) in material from the lesions or by culture. Treatment formerly consisted of 4 gm. of sulfadiazine a day for life, but amphotericin B offers hope of clinical cures.

Keloid blastomycosis. This disease, also

en la companya de la

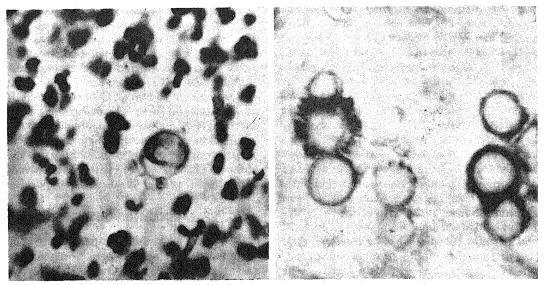

Figure 213. Left, giant yeast cell of Paracoccidioides brasiliensis showing multiple buds in skin section. Periodic acid-Schiff hematoxylin; × 400. Right, keloid blastomycosis. Chains of round cells in skin. Gridley stain; × 400.

called Lobo's disease, has also been described in South America. It is characterized by a budding yeast in chain-like formation. The tissue reaction is exaggerated fibrous hyperplasia leading to keloid formation. The organism called *Loboa loboi* has not as yet been cultured.^{21, 229}

HISTOPLASMOSIS165, 223

This organism was discovered in 1906 in Panama by Darling, who observed it in sections of tissues taken postmortem from three cases of what appeared to be visceral leishmaniasis and named it Histoplasma capsulatum. The first case in the United States was reported in 1926. The actual number of infections is undoubtedly many more than is indicated by reports of cases. Healed lesions of pulmonary infections are frequently found at autopsy in areas where the disease is prevalent,4 and the prevalence of the infection is shown by skin testing for hypersensitivity to the substance of the microorganism.70 It is now believed that in the United States 30 million people have or have had histoplasmosis; most in the Ohio and Mississippi River valley areas.4,72 The disease has been studied most intensively in this country, but apparently its distribution is world-wide. 42, 161

The causative organism. The organism appears in the tissues as a small, oval, yeast-like cell 2 to 4 μ in diameter with the ap-

pearance of a capsule, although there is none.41 In tissue stained with Giemsa stain it is difficult to distinguish the organism from that of leismaniasis except for the karyosome bar in the latter. Larger strains, up to 15 µ in diameter, are found in African histoplasmosis¹⁷³ (H. duboisii) and have been observed on occasion in this country. In stained preparations the central stained mass is surrounded by a clear zone. The organism is usually intracellular, in the mononuclears in the peripheral blood and in the macrophages elsewhere, especially those of the bone marrow and spleen. Because of this characteristic intracellular position of the parasite, the disease is sometimes called reticulo-endothelial cytomycosis or simply cytomycosis. 112 The common world-wide histoplasmosis is caused by H. capsulatum. The African form differs by its larger yeast form (H. duboisii). A third species, H. farciminosum, causes farcy in horses and is found around the Mediterranean area. It differs from the other two in having smooth chlamydospores in its saprophytic stage. The perfect stage of H. capsulatum is called Gymnoascus monbreuneii and is closely related to the dermatophytes.

The microorganism is cultivable from the blood or biopsy specimens, or it may be isolated from the sputum in pulmonary infections by animal inoculation during the course of the disease, and from various organs and tissues at autopsy in fatal cases.

It grows in the yeast-like form seen in the tissues in sealed blood agar cultures at 37° C. and in tissue culture, $^{111, 113, 139}$ but on Sabouraud's cycloheximide agar a mycelial form is assumed and the colonies are mold-like, white, and cottony with aerial mycelium when incubated at 25° C. 156 Chlamydospores (macroconidia) are formed in abundance, at first smooth and pyriform, but as they mature they become larger, 7 to $15~\mu$ in length, thickwalled, and tuberculate with finger-like protuberances sometimes as much as $6~\mu$ long.

Pathogenicity for man. Three types of diseases are generally recognized.29 The acute pulmonary type is characterized by sudden onset of malaise, fever, cough, chest pains, chills, sweats, and dyspnea, ranging in severity from severe flu syndrome to subclinical involvement. In this most common form the attack is followed by quick recovery and a fairly strong immunity. Progressive disease occurs in only 0.1 to 0.2 per cent of cases. The focal granuloma is associated with lymphadenitis of the hilar lymph nodes which then heals, often with calcification, and leaves a lesion roentgenographically identical to those of tuberculosis.221 In all its forms, histoplasmosis mimics tuberculosis.

The second type of disease, chronic progressive pulmonary histoplasmosis, may present as an exaggeration of the symptoms given above. It is usually found in middleaged males and is heralded by a persistent

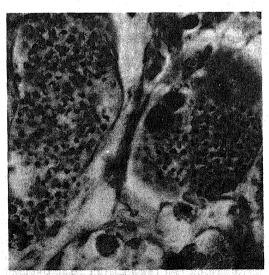

Figure 214. Histoplasma capsulatum. Yeast-like cells in macrophages of the bone marrow in systemic histoplasmosis. Hematoxylin and eosin; × 1000. (Humphreys.)

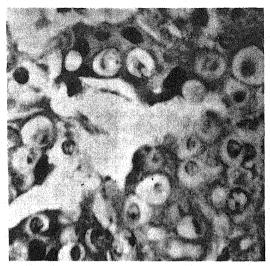

Figure 215. Giant yeast cells. of *Histoplasma duboisii*. African histoplasmosis. Hematoxylin and eosin; × 800.

complement fixation test. The disease progresses, like tuberculosis, to necrosis, caseation, and cavitation. The process is usually very slow.

The third form of the disease is disseminated histoplasmosis, which may develop at any age, but is commonly seen in infants or children. It has a rapid, fulminating, fatal course. Affected children are usually physiologically defective. This form of the disease is also seen in older people, particularly poor-risk patients, who may have lymphoma, Hodgkin's disease, diabetes, etc. The third patient-type seen is the patient with an old pulmonary infection which disseminates either by extension or reinfection. Dissemination may involve any organ, but especially the spleen and liver. The first clinical signs may be lesions on mucocutaneous areas.

Though it is sometimes implied that histoplasmosis is always a generalized infection of the macrophage system, the parasites being especially numerous in tissues rich in these cells such as the spleen and bone marrow, this is by no means generally true. In most cases there are nodules or extensive areas of necrosis in one or more organs, but in some instances only a single organ, such as the adrenals, has been infected. These necrotic lesions usually consist of a central area of necrosis surrounded by granulation tissue containing large numbers of macrophages and ingested parasites. In some instances the parasite has been found to be limited to such areas, while in others it is

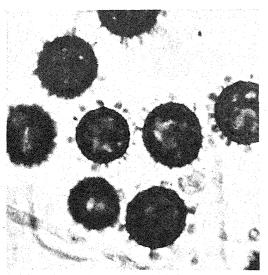

Figure 216. H. capsulatum. Mycelial stage showing tuberculate macroconidia (chlamydospore) and microconidia. Lactophenol-cotton blue; × 400.

widely distributed in the macrophage system as well. Infection of the central nervous system is relatively rare but has been observed. The statistical distribution of the lesions of the disease has been summarized by Schulz.²⁰⁰

Experimentally infected animals give a positive reaction to the intradermal inoculation of a preparation of liquid culture of H. capsulatum analogous to old tuberculin and coccidioidin and designated histoplasmin. In areas in which the disease is endemic, positive reactions are correlated with the incidence of pulmonary calcification in tuberculin-negative individuals. The association of positive histoplasmin reactions with calcified nodules in the lungs suggests that, as in the case of coccidioidomycosis, histoplasmosis is not a rare, highly fatal disease, but one which is widespread in certain geographical areas in a mild pulmonary form. That such reactors are or have been actually infected is difficult to demonstrate on any large scale, but infection has been shown in a sufficient number of cases to strongly support such an inference. Precipitins are produced early in the disease and disappear fairly rapidly.172 The complementfixing antibody titer rises somewhat later and disappears later, usually by 5 to 7 months. If the complement-fixing titer persists or rises, the prognosis is poor. Precipitating antibodies demonstable by the gel diffusion technique are also present. Two lines may be formed: the so-called M line, near the antigen well, indicates experience with the disease, and the thin H line nearer to the serum well correlates with active disease. 199 The fluorescent antibody technique is useful in the diagnosis of histoplasmosis. 129

The treatment of choice is amphotericin B in the usual course given for systemic fungous disease, 1 mg./kg. body weight to a total of 1 to 5 gm. The agent X5079C, now called Saramycin, holds hope of being a better overall therapeutic agent. There are some severe side affects from amphotericin B therapy. 15, 25, 44, 108

Pathogenicity for lower animals. A variety of animals have been found to be naturally infected, including dogs and cats, wild rodents, and other wild animals.45 An association with bats and bat caves⁴⁶ has been well established. The microorganism has been isolated from bat tissue.204 but the role of these animals as a reservoir and in the dissemination of the infection remains to be determined. It is improbable that these represent an animal reservoir of human infection; rather the fungus appears to be a saprophytic form, living in the soil from which it has been frequently isolated, which infects both man and animals. Mice have, in fact, been infected experimentally by exposure to soil contaminated with the microorganism.¹⁰⁷ Experimental animals are infected with some facility, a localized lesion being produced at the site of subcutaneous inoculation in guinea pigs and rabbits and generalized infection in dogs and rats. Both yeast-like and mycelial forms are infectious experimentally.

Epidemiology. The infection is airborne and is contracted by inhalation. Infection is associated with point sources such as chicken coops, pigeon roosts, starling roosts, bat-infested caves, and old decaying wooden structures where excreta and other decomposing organic matter under conditions of high humidity provide a nidus of infection. The infection tends to occur in rural areas and in low-lying river country. There is a large endemic area of infection in this country in the area including Missouri, Tennessee, Kentucky, Arkansas, adjacent areas in adjoining states, in which the proportion of positive reactors to the histoplasmin test ranges from 50 to over 90 per cent. This is in sharp contrast with the area from the Great Lakes to the Pacific coast and from Colorado to the Canadian border, in which the proportion of reactors is less than 2 per cent. Within the endemic area the proportion of reactors increases with age, from 5 per cent at two years, through 60 per cent at 18 years, to 75 to 90 per cent at age 55 and over.

Histoplasmosis is found in Africa, where it is known as cave disease because it has often been contracted in caves infested with bats. It differs slightly from American histoplasmosis. 163 Only sporadic cases have been reported from Europe. Consistent with this, the reactor rates are less than 2 per cent except in occasional isolated areas, such as Burma and northern Italy, where rates as high as 20 per cent have been observed.

Diagnosis. Microscopic demonstration of the fungus is highly suggestive of the disease, but culture and identification are reguired to establish the diagnosis. H. capsulatum has been isolated by blood culture in generalized infections and from biopsy specimens; sternal puncture may prove useful. It may be isolated fairly easily from sputum in cases of pulmonary infection by intraperitoneal inoculation of mice. The recommended procedure is to put the specimen on cycloheximide blood-agar and incubate at 25° C. Examination for characteristic tuberculate chlamydospores and demonstration of dimorphism at 37° C. establishes the identity of the organism.

OTHER SYSTEMIC MYCOSES

CRYPTOCOCCOSIS143

In medical literature the term blastomy-cosis has been used very loosely to designate etiologically diverse infections in which budding cells are found in the tissues. Confusion arises largely between European blastomycosis, which will be considered here, and American blastomycosis, taken up in a previous section.

Aside from candidiasis, two general types of yeast infection may be distinguished, the one with deep-seated cutaneous or subcutaneous infections which tend to become generalized, and the other with infections of the central nervous system arising, as a rule, by metastasis from foci in the lungs. The first of these is known as European blastomycosis and the second as torula meningitis. Both are caused by the pathogenic yeast Cryptococcus neoformans.

European blastomycosis. What was probably the first case of yeast infection of proved etiology was a fatal generalized infection observed by Busse and by Buschke in 1893, which they called systemic blastomycosis and which subsequently has been generally known as European blastomycosis. From primary ulcers on the face and neck, the infection spreads to the cervical lymph nodes, and the causative organism was isolated first from a secondary tibial abscess, then from the primary ulcers, and shortly before death from the blood stream. Other cases reported since are of this general type, characterized by deep-seated ulceration of the skin, 166 sometimes granulomatous, and there may be infection of the viscera, usually secondary, involving the spleen, liver, kidneys, and mesenteric lymphatics. Infection of the lungs may be primary, may occasionally be arrested with no further manifestations, or may spread from the focus in the lungs; lung infection may also be secondary.

The microorganisms are found in exudates and in mucoid masses of gelatinous material as round to oval cells, 5 to 6 μ in diameter, surrounded by a mucilaginous sheath. The gelatinous material in which they may be embedded is evidently a product of the fungus. It is reported that the cells may be stained specifically in tissue sections and smears by the fluorescent antibody technique. They are readily cultivated on most ordinary mediums as a smooth white or very light tan colony without distinguishing features. The organism will not grow on mediums containing cycloheximide.

Cryptococcus meningitis. A number of cases of yeast etiology have been reported, the great majority from this country. The clinical features of the disease set it off from European blastomycosis, for the infection is predominantly one of the central nervous system, and the skin is seldom involved. The symptoms are those of brain involvement, especially intracranial pressure. Brain tumor may be closely simulated in some cases, and the disease develops slowly, usually without febrile reaction or other signs of infection; a case of 16 years' duration has been reported. The pathological picture is that of chronic leptomeningitis with thickened meninges adherent to the cerebral cortex and showing diffuse or focal granulomatous lesions. The cerebral cortex is invaded in about half the cases; the lesions are sometimes granulomatous but

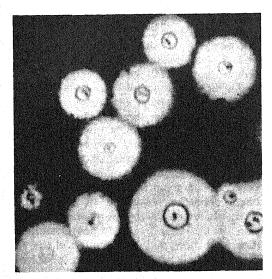

Figure 217. India ink preparation of *Cryptococcus* neoformans. Yeast cell in center surrounded by capsule. × 800.

more often cystic, and there is little if any inflammatory reaction. The granulomatous lesions of both meninges and brain contain large accumulations of macrophages which phagocytose the fungus, while the cystic lesions consist of enormous numbers of yeast cells embedded in a gelatinous matrix. The yeast is usually present in the spinal fluid in pure culture and may be observed in wet unstained preparations of the centrifuged sediment in a drop of India ink. The lung and kidney are the next most frequently involved organs, but any tissue may be attacked, with generalization of the infection.¹⁸ There is a strong association of cryptococcal infection with such debilitating diseases as lymphomas and leukemias, and such patients run a particular danger of a rapidly fatal infection. There is reason to believe that infection is more common than has been supposed, perhaps 2000 for every proven case, and that the portal of entry is the lung. Unlike histoplasmosis, blastomycosis or coccidioidomycosis, there is so little tissue reaction that a skin test has not as yet been developed. Current estimates indicate 15,000 subclinical or clinical cases per year in New York City alone. It is almost always fatal in untreated cases, but amphotericin B therapy has been reported to be effective. 11, 71, 175

Pathogenicity for lower animals. Infection occurs in lower animals, notably in the lungs and nasal granulomata of horses, and

cryptococcus has been described as the etiological agent in a severe outbreak of bovine mastitis, but there is no reason to believe that lower animals constitute a reservoir of human infection. The organism has been isolated from soil,3 and it seems probable that this is the source of both human and animal infections. There is a close association of the organism with pigeon droppings. 124, 142 In areas crusted with bird dung, such as sills, ledges, attics (but infrequently in enriched soil), the organisms can easily be found if looked for, and in large numbers. Point source infections have been documented in New York¹⁴² and Chicago¹⁷⁶ as well as many other places.232 The organism does not appear to be in the pigeon body itself, just in the filth left by the bird. The microorganism is virulent for mice with an LD₅₀ of about 1000 cells on intracerebral inoculation; following intraperitoneal inoculation it produces a generalized infection that spreads to the central nervous system. Experimental infection has also been produced in marmosets (Leontocebus geoffroyi) by feeding them large numbers of the microorganisms.225 Some immunity has been achieved in experimental animals,1 but effective antibodies in human infections are highly debatable.^{73, 74} Serological procedures for diagnosis are not reliable, except for the fluorescent antibody technique on tissue sections. 128 A nonantibody anticryptococcal

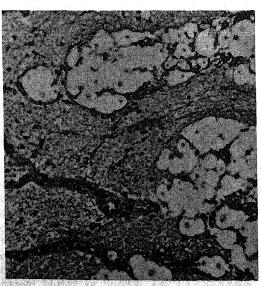

Figure 218. C. neoformans in optic nerve. Spaces represent areas occupied by capsular material. Periodic acid-Schiff hematoxylin; × 400.

factor in human serum has been reported. 114 A skin test is being developed. 194

The causative organism. For some time the relationship of these clinically diverse infections was not realized, and the yeast of European blastomycosis was known as C. hominis and that of torula meningitis as T. histolytica. In 1934, however, Benham showed that strains of the two yeasts were substantially identical, the difference in pathogenicity being one of degree only. Similar observations have been reported by others. It seems established, therefore, that these diseases are caused by the same etiological agent and, furthermore, that only a single species of yeast is involved, observed strain differences having no more than variant status.

It characteristically assimilates (but does not ferment) glucose and sucrose, not lactose or melibiose. It is the only member of the genus pathogenic for mice. The genus members characteristically produce urease and this, together with their lack of mycelium production, separates them from the genus Candida. C. neoformans (C. hominis, Debaromyces neoformans, Torula histolytica) is the only pathogen in the genus. A nonpathogenic variety, C. neoformans var. innocuus, and several other species, including C. laurentii, C. mucorugosus, and C. luteolus, are accepted as valid species,16 but differ from C. neoformans in the above physiological tests. The heavily encapsulated forms are poor immunizing antigens, but satisfactory antiserums may be prepared in the rabbit with poorly encapsulated forms. The organism gives a Quellung reaction in homologous antiserum. There are at least three immunological types, designated A, B, and C by Evans, 57, 58, 59 depending upon the polysaccharide capsular antigen. The polysaccharides are closely related chemically, all containing xylose, mannose, galactose, and a uronic acid.

Torulopsosis. Torulopsis glabrata was isolated from animal infection in 1939. It is a small (3 to 4μ) intracellular parasite, and infection in tissue somewhat resembles histoplasmosis. The organism is fairly commonly isolated from urine and may be involved in infections. ¹²¹ It has been isolated from uncomplicated meningitis as the cause of death. The organism is like Cryptococcus, always in a yeast form. It produces a pasty white to gray colony, ferments glucose (acid and gas), and assimilates only glucose. A similar species, T. pintolopesii is found in

the mouse alimentary tract and may lead to confusion in experimental infection by human pathogenic fungi.

Geotrichosis. Geotrichosis is an infection of the oral, intestinal, bronchial, or pulmonary system by a semiyeast organism, Geotrichum candidum.28 The nomenclatural synonomy and relationships, even if there is only one species, are much debated. Geotrichosis seems to have been differentiated from candidiasis in 1842. Bronchial geotrichosis is a rare but fairly well delineated entity. Chronic bronchitis with persistent expectoration of mucoid sputum and with little or no rise in temperature is the general symptomatology. Oral geotrichosis resembles oral candidiasis, as does the rarely reported beer yeast (Saccharomyces cerevisiae) oral and bronchial infections. Other sites of infection have been reported, but the status is provisional as the organism is a common contaminant. It is easily isolated from feces, cottage cheese, and tomatoes. The colony is a white, mealy, and barrelshaped arthrospore similar to Coccidioides (but lacking the empty space between cells) and can be seen under the microscope.

ASPERGILLOSIS

The common blue-green mold seen on damp bread, bacon, or most any organic material is usually a member of the genus Aspergillus. The other common blue-green fungus is Penicillium species. Together these organisms constitute the most omnipresent and ubiquitously distributed molds in the world. With every breath we inhale some spores of one or more species. Most of the time these spores are disposed of without injury to the host. In some individuals and under certain conditions, these organisms may provoke injury to man in one of two ways: allergic response to the presence of the spore or, much more rarely, invasion of pulmonary or other tissue.

Of the two groups, Aspergillus is more commonly associated with infection than Penicillium, and one species, A. fumigatus, is highly pathogenic for birds and also occasionally for man. There are over 70 species of the genus Aspergillus, of which a dozen or more have been described as responsible for infection. Of the more than 140 species of Penicillium only a few have been isolated from the very rare disease penicilliosis. Though the genus names are

in the family Moniliaceae, order Moniliales of the Fungi Imperfecti, a few of each genus produce a sexual stage. The sexual spore is an ascus and the group, therefore, is in the class Ascomycetes, order Eurotiales.

Pathogenicity for lower animals. Aspergillosis of domesticated birds, pigeons, ducks, penguins, and chickens is not uncommon and at times assumes economic importance. Three types of infection commonly occur; infection of the air sacs and both nodular and pneumonic forms of lung infection. A fourth type, aspergillar meningitis, is found with some frequency in certain host groups, i.e., penguins. Infection of the air sacs takes the form of a superficial infection of the epithelial lining, which becomes thickened and covered with a mat of green sporulating mycelium. In the nodular form of the disease, tubercle-like masses of infiltrated tissue, necrotic in the center, are formed. A diffuse infiltrate is formed in the pneumonic form, and the lung tissue is consolidated and grayish white in color. The pneumonic disease sometimes assumes epidemic form in chicks and is known as "brooder pneumonia." The source of infection is usually moldy grain or straw. The fungus may also invade the egg during incubation, with infection of the embryo. Cattle, sheep, and especially horses develop aspergillosis, though less commonly than birds. The lesions are pulmonary and may be either nodular or pneumonic.

Strains of infectious aspergilli vary widely in their pathogenicity when tested by inoculation of experimental animals. In general, those isolated from infections are quite virulent, while those found in air and elsewhere are of low virulence. With virulent strains a fulminating, rapidly fatal pneumonia may be produced in pigeons by inhalation of spores, while the feeding of grain overgrown with the mold often produces an infection of the air sacs. Intravenous inoculation of pigeons results in an acute infection with multiple miliary abscesses, especially in the lungs, if the dose is not too large. Otherwise, rapid toxic death occurs. Rabbits inoculated intravenously with spore suspensions of virulent strains usually die in three to five days, with multiple abscess formation, notably in the kidney, whereas subcutaneous or intraperitoneal inoculation produces localized lesions which may or may not be fatal. The subject of Aspergillus pathogenicity is one of the most enigmatic in the study of the fungi. Some isolates of a species can be injected in large numbers and produce no disease; other isolates of the same species are as virulent or more so than *Coccidioides immitis*. Many Aspergillus and Penicillium species can be induced into a yeast-like growth similar to that of *Blastomyces dermatitidis* in which they are very invasive for the deep organs of experimental animals.¹⁸⁰

Pathogenicity for man. Human cases of aspergillosis are most frequently infections of the external ear (otomycosis). The disease varies from a plugging of the external meatus with a mass of mycelium to ulceration of the walls and even penetration of the middle ear; the mild cases are the most numerous. It is fascinating to look through an otoscope and see the external auditory canal lined with the delicate, beautifully architectured fruiting heads of an Aspergillus. While A. fumigatus is the most common invader, A. nidulans, A. flavus, and A. niger are sometimes found.

Pulmonary infection is relatively uncommon in man, more cases appearing in Europe than in the United States. It occurs in two forms, the first, an intracavitary fungous mass, "fungous ball" or aspergilloma, 186 and the second, bronchopneumonic aspergillosis. 30, 85, 164 In the former, there is little frank invasion of living tissue, and the disease may manifest itself as an extreme allergic response to the presence of the mold. In the latter type, invasion of tissue and more serious disease occur, frequently resulting in death. Infections of both types may be secondary to tuberculosis, other pulmonary fungous diseases, neoplasms, or cytopathic drugs. It is of some interest that the primary infection has been classed as an occupational disease with regard to compensation. The disease is clinically similar to and may be mistaken for tuberculosis, neoplasm, or histoplasmosis; there may be extensive cavitation and it may advance rapidly. The mycelium may be found in the sputum and the fungus is readily isolated by culture (not on cycloheximide agar) but all other etiological agents must be excluded and great caution must be exercised before attributing an infection to such common contaminants as aspergilli. 109 Many lung infections have been reported in grain handlers, millworkers, and bird-fanciers, especially those having to do with the care of pigeons; there is convincing evidence that transmission of the disease from pigeons to man can take place.

Very rarely aspergillosis may take other forms in man. The occurrence of Aspergillus in maduromycosis has been noted, and a case of chronic suppuration with discharge of grains has been reported. Rarely it may assume an acute disseminated form, including involvement of the central nervous system. 94 It is not infrequently isolated as the cause of keratitis of the lens following a puncture wound of the eye. A precipitin test has been developed. 218

A final word must be said about the constant danger of aspergilli and other common soil fungi to debilitated patients. A. fumagatus is a thermophilic fungus, growing well at 37° C., and it also produces a potent endotoxin. 104 It and many other saprophytes readily invade patients on cytopathic drugs, nitrogen mustard, antimetabolites, or antimune drugs (Imuran) or patients with debilitating diseases, particularly neoplasms, less so diabetes. 97 Many organ-transplant failures have resulted from infection by "saprophytes." 224 Treatment of choice is amphotericin B. 174

MUCORMYCOSIS 157

Mucormycosis has been a very rare infection, occurring largely as a mycotic complication of chronic debilitating disease, most often uncontrolled diabetes but also amebic colitis and kwashiorkor.^{48, 228} With the introduction into general use of therapeutic agents such as antibiotics, corticosteroids, and antileukemic drugs the infection has been found more often, so much so that it is considered to be a "new disease."¹⁰

The fungi, usually species of Rhizopus, are apparently of very low virulence and are able to invade the tissues only when natural resistance is markedly reduced. Infection usually begins in the upper respiratory tract, most often the nose, where spores germinate and the mycelial growth invades the mucous membrane and may extend into the adjacent sinuses, orbital cavity, or cerebral tissue.87 Primary infection may also occur in the lung, where growth on the bronchial mucosa penetrates the wall to the hilar tissue or a lobar pneumonia may result. The fungus appears to have a special affinity for arteries, with penetration into the lumen to produce thrombosis and infarction,

Figure 219. Mucormycosis showing broad nonseptate mycelium in brain tissue. Periodic acid-Schiff hematoxylin; × 800.

and may reach the central nervous system via ophthalmic and internal carotid arteries to produce a meningo-encephalitis. In tissue the organism appears as broad, distorted, nonseptate hyphae. Most cases are diagnosed at autopsy; the tissue having been thoroughly soaked in formaldehyde and no cultures obtainable. Most species grow readily on mediums without cycloheximide. Members of the genera Mucor, Absidia, and Rhizopus have most often been isolated. They are members of the order Mucorales of the class Phycomycetes. Other phycomycete diseases have been discussed and, in order not to confuse the entities, the proposed change of name to phycomycosis is not followed. The clinical pictures are quite different.122

MISCELLANEOUS MYCOSES

Various other fungi have occasionally been described as producing human disease. Though hundreds of fungus species have been recorded as isolated from lesions, it is quite difficult to assess their significance in the disease process. If the organism is isolated more than once and in quantity from exposed lesions or sputa and all other etiologies have been ruled out, it may be considered as responsible. However, if the organism is isolated from a closed body cavity, lesion, or blood culture, it must be

considered as a strong suspect in the disease process. Below are listed some rarely encountered fungous diseases in which fungi have been isolated with sufficient frequency to establish their potential invasive ability.

Penicilliosis. The ubiquity of species of Pencillium and their constant contamination of instruments, wounds, urine, sputum, etc., makes the establishment of this diagnosis very difficult. P. marneffei is found as a veast-like invasive pathogen of Asian rodents. Substantiated infection of the cornea and the external ear, a few mycetomas, and a very rare pulmonary infection are recorded for a variety of Penicillium species. The pathological picture is similar to aspergillosis. The related genus Scopulariopsis, especially S. brevicaulis, is a not uncommon agent of onychomycosis and peronychia, characterized by much inflammation and pus.

Cercosporamycosis. Cercospora apii,⁵¹ a common plant pathogen (black streak of onion, celery blight), has been the cause of a subcutaneous, indurated, verrucous infectious process. Brown mycelium is seen in tissue. The cases reported thus far have been from Indonesia.

Cladosporiosis. Species of the genus cladosporium, especially C. trichoides, have been isolated several times from cerebral and pulmonary lesions. Many cases have been fatal, and the disease is called black degeneration of the brain for its most apparent pathological picture. The lesions usually are localized and encapsulated. In tissue sections, multiseptate, brown, distorted hyphae are seen. The organism (a Dematiaceae, Fungi Imperfecti) grows well as a black velvety colony on mediums without cycloheximide. It is pathogenic for experimental animals and is neurotropic. 130

Mycotic infections of the eye. Introduction of fungal spores into the cornea by abrasion or secondary to herpetic lesions is not an uncommon occurrence. Establishment of the infection is enhanced by the overuse of steroids.56 The organisms involved are most often soil saprophytes, such as Aspergillus, Fusarium, and Hormodendrum.80 The infection is usually localized but may destroy the cornea or spread to the rest of the eye. Hematogenous spread of pathogenic fungi from other loci to the eye is known but is very rare. A condition, histoplasma uveitis, is recognized by ophthalmologists, but a causal relationship to Histoplasma capsulatum has yet to be demonstrated. 192, 215 Treatment of corneal infection is usually with irrigation of Nystatin or amphotericin B solutions.

MYCOTOXICOSIS

The ingestion of particular fungi or products elaborated by particular fungi sometimes leads to a variety of distresses to the individual. The distress may range from nausea (Russula emetica),13 hallucination (Psilocybe species), and severe dermatitis (Pithomyces species) to carcinoma (Aflatoxin) and death (Amanita phalloides). The fatal toxicity of certain mushrooms was well known in ancient times. Agrippina was familiar with several poisonous agarics and the dosages necessary for the desired end. More recently, the endotoxins of aspergilli were investigated by Henrici, in the 1930's. At present there is renewed interest in this subject because of the potential carcinogen found in foodstuffs infected with Aspergillus flavus and the recreational use of hallucinogenic drugs such as psilocybin and d-lysergic acid (from Claviceps purpurea).

Aflatoxin. A chloroform-soluble, small molecular weight substance elaborated by Aspergillus flavus and A. parasiticus known as aflatoxin is regularly able to induce hepatomas in ducklings and rats. 170 There have been widespread epidemics of high mortality among stock animals following ingestion of moldy feed, particularly peanuts, corn, or peas. The disease has been reported from all parts of the world and affects a variety of animals; cattle in Africa, "X" disease of turkeys, etc. The toxin has an empirical formula of C₁₇H₁₂O₆ and is structurally related to synthetic coumarin with a dihydrofuran substitution. It can be detected easily by characteristic fluorescence and by hepatoxic changes in ducklings. Embryonic lung cell tissue culture can detect as little as 0.01

 μ g. of aflatoxin B.

Mushroom poisoning. Ford in 1923 recognized five types of mushroom poisoning which appear to be still valid. 49

Mycetismus gastrointestinalis. The chief complaint in this mildest form of mycotoxicosis is nausea, which may be followed by vomiting and diarrhea. Spontaneous recovery usually occurs in one to two days. This type of "poisoning" is particularly

common in children following ingestion of the orange jack-o-lantern mushroom, Clitocybe illudens. Many other species will produce the same syndrome, for example, Russala emetica, Boletus satanas and other boletes, Entoloma lividum, and Lepiota morgani. L. morgani has been responsible for a few deaths.

Mycetismus choleriformis. This is the most serious and often fatal type of intoxication. The death angel (Amanita phalloides), the destroying angel (Amanita verna), and probably other Amanita species produce a heat-stable, bicyclic hexapeptide, phalloidin. It is one of the most potent toxins known. The course of symptoms is similar to that in phosphorus intoxication and may appear six to 18 hours following ingestion. Abdominal pain, vomiting, diarrhea, bloody stool with mucous strands, protein and casts in urine, malaise, and cyanosis may have a fatal outcome in two to three days. Temporary remission and relapse may also occur. Treatment includes complete evacuation of the alimentary tract, opiates, intravenous glucose in saline, and rest. Hygrophorus conicus and Pholiota autumnalis may also induce a similar disease—usually milder.

Mycetismus nervosus. Muscarin is a heatstable, substituted quaternary ammonia (related to choline) which excites the parasympathetic system. It is found in Amanita patherina and A. muscaria. Symptoms occur within one to three hours after ingestion and may include tearing, sweating, salivation, retching, peristent peristalsis, vomiting, diarrhea, contraction of pupils and ciliary muscles, acute excitement, delirium, and coma. Treatment includes gastric lavage and atropine. These fungi have been used since ancient times in Sweden and Sibera as intoxicants. Inocybe infida, I. infelix, and Clitocybe illudens give milder types of a similar disease.

Mycetismus sanguinareus. A heat-stable hemolysin is found in Helvella esculenta and other Helvella species. Hemoglobinuria, abdominal distress, and jaundice may occur. Hemolysins are present in several fungi but are usually destroyed by digestion or heating.

Mycetismus cerebris. Hallucinogenic intoxication occurs following the ingestion of several fungi. The active principle is usually a small molecular weight substance related to indol (viz., d-lysergic acid, psilocybin). These psychodelic or psychotropic

mushrooms have been used for centuries in certain Mexican communities in religious rites. They have recently become popular as sensory- or perception-heightening agents among certain segments of society who refer to their use as a "trip"! Many species of the genera of the brown-spored mushrooms such as Paneolus, Psilocybe, Stropharia, and Conocybe may contain varying amounts and types of the hallucinogenic agents.

Many other types of toxic conditions may result from the ingestion of various fungi or their products. Ergot of rye (Claviceps purpurea) results in blackleg (a hemorrhagic disease), ergotism, confusion, and death following ingestion in flour or feed. Numerous pharmacologically active substances are produced by this organism, including lysergic acid and ergotamine. Stachybotrys toxicosis results from eating moldy forage infected with Stachybotrys alterans. Desquamation of epithelial linings, leukopenia and fever may lead to death in one to five days in severe cases. The disease is most prevalent in the Ukraine. Alimentary toxic aleukia may result from grain or forage infected with Fusarium sporotrichoides or F. roseum. The symptoms are similar to Stachybotrys toxicosis. A disease of sheep called facial eczema results from ingestion of the grass Sporidesmium bakeri infected with the mold Pithomyces chartarium. The active ingredient is sporidesmin, which has an empirical formula of $(C_{19}H_{21}O_6N_3S_2Cl$ C Cl₄). Red clover hay infected with Rhizotonia leguminicola causes excessive salivation in foraging animals.37 The active principle is a parasympathomimetic alkaloid. Many other toxins of varying importance have been described from many fungal species.

AND STATE OF THE S

Chapter Thirty-three

THE SPIROCHETES

Spiral shaped microorganisms were for a long time grouped together indifferently under the common name of spirillum, spirochete, or vibrio. Further knowledge has shown that some of these are true bacteria. although curved, and such forms are now placed with the bacteria in the genus Vibrio and various species of Spirillum. Others, however, possess characteristics which distinguish them from curved bacteria, such as the cholera vibrio, and also from the actively motile protozoa, such as the trypanosomes. Like the bacteria, the spirochetes multiply by transverse fission, have no well-defined nucleus, and do not exhibit anterior-posterior polarity. They appear to be more closely related to the true bacteria than to the protozoa and may, perhaps, be regarded as a connecting link between the two. 107

Classification and nomenclature within the group are still in an uncertain condition, and there is by no means general agreement regarding the separation of some of the genera. These microorganisms are difficult to cultivate on artificial mediums in many cases, and little or nothing is known of their physiological characteristics; the genera are separated from one another on a purely morphological basis.³⁰ Studies by electron microscopy have tended to confirm the soundness of the morphological criteria.¹⁰²

Although the name spirochete is commonly used to designate those forms which are classified as members of the family Spirochaetaceae, the generic term Spirochaeta was originally proposed by Ehrenberg for the large free-living forms he described. A second genus, Cristispira, is characterized by the presence of a membranous appendage or crista wound about the body of the cell and is made up of microorganisms found living as saprophytic commensals in certain molluscs. A third genus. Saprospira, consists of free-living forms which differ from Cristispira in that the crista is absent. The other genera contain the spirochetes which are pathogenic for man and animals: Borrelia, the spirochetes of the relapsing fevers; Leptospira, the spirochetes causing Weil's disease or infectious jaundice and certain fevers; and Treponema, the spirochetes of syphilis and vaws.

The Spirochetes of the Relapsing Fevers

(Borrelia)³⁷

The relapsing fevers are a group of closely related infections characterized clinically by an initial pyrexia of three to four days' duration, followed at intervals of a few days by successive relapses. They are widely distributed and occur in every country of the world with the possible exception of Australia. The microorganisms responsible

for these diseases are spiral forms, first observed by Obermeier in 1873 in the blood of patients with European relapsing fever.

Morphology. The basic structure of these spirochetes is a spring-like axial filament upon which there is a layer of contractile protoplasm enveloped in a delicate periplast. The terminal filaments are, per-

haps, drawn-out ends of the periplast or nonrigid and noncoiled ends of the axial filament. Attached spherical bodies are sometimes observed. The cell rotates as a consequence of the stretching of the axial filament by the pressure of contracting protoplasm. When there are rapid and successive contractions and relaxations, the microorganism rotates rapidly and moves in one direction or another according to the direction of the rotation. In the relaxed state the spirals are regular and even; the larger the cell the heavier the axial filament and the greater the distance between the spirals. The regularity of the spirals is disturbed by the contracting and relaxing protoplasm in the actively motile cells. The various species cannot be distinguished from one another on a morphological basis. All are 0.2 to 0.5 μ in breadth by 10 to 20 μ in length. They are best stained by the Romanowsky method or some modification such as Giemsa, but, in contrast to some of the other spirochetes, Borrelia may be stained with the ordinary aniline dyes.

Cultivation. The spirochetes of relapsing fever were cultivated by Noguchi in 1912 in a medium of ascitic fluid and fresh tissue in which a network of fibrin is formed. A semisolid serum agar has been used also. In culture the spirochetes are aerobic, and the paraffin-oil seal frequently used prevents evaporation rather than interferes with the diffusion of oxygen. While such successful cultivation has been reported, the spirochetes are exceedingly difficult to grow in initial culture and cannot be maintained in serial passage; it is not unlikely that they only persist for a time in such mediums and never have been actually cul-

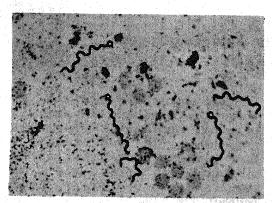

Figure 220. Borrelia recurrentis in a blood smear from an infected rat. Fontana stain; × 1160. (Freeman.)

tivated. They may be grown in the developing chick embryo, however, and have been isolated directly from human infections in this way.^{14, 85}

Classification. The relapsing fever spirochetes have been given the generic name Borrelia. The validity of this degree of differentiation from the spirochetes of syphilis and yaws, Treponema, is open to some question, and the relapsing fever spirochetes are regarded by many as Treponema species. It was pointed out by Noguchi that the relapsing fever spirochetes do not differ more from *Treponema pertenue* (yaws) than that microorganism differs from *T. pallidum*.

It is not clear to what extent the relapsing fever spirochetes can be divided into species. It is probable that in many cases those given species rank are, in fact, only strains or varieties. In many instances these have been given place names or named after some individual worker, but the differentiation has been geographical rather than biological. These forms are immunologically heterogeneous and unstable in that they are modified in character by residence in different insect or mammalian hosts. Cross-immunity tests, therefore, are not useful. It has been suggested that they are differentiated on the basis of pathogenicity or insect host, but there appear to be no reasonable definite lines of demarcation possible on these bases. In general, then, the questions of interrelationship and speciation of these organisms are almost completely open but most workers agree that, although they are all immunologically related, there is too great heterogeneity to justify regarding the various strains as no more than varieties of a single species Borrelia (Treponema) recurrentis.

Pathogenicity. Relapsing fever is an ancient disease, and one of the first epidemics was described by Hipprocrates as occurring on the island of Thasos 2000 years ago. It was not mentioned for many centures, and then there was a tendency to confuse it with louseborne typhus fever with which it may occur. The Yellow Plague that followed the pandemic of bubonic plague in the time of Justinian was probably relapsing fever, and an epidemic in Ireland in 664 was described by the Venerable Bede. At the present time it occurs sporadically in various parts of the world.

As indicated above, the relapsing fevers constitute a group of closely related dis-

BORRELIA 747

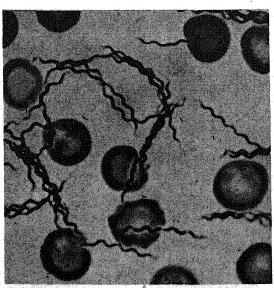

eases. The spirochete observed by Obermeier was that of European relapsing fever. a disease which has been known since the early part of the eighteenth century and has at times prevailed extensively in parts of Europe. The causal microorganism is designated Borrelia (or Treponema) recurrentis. Four forms of relapsing fever occur in Africa; the spirochete of the form in Central Africa is B. duttonii, which is also found in the Middle East1; that of the East African disease B. kochii; that occurring in northern Africa,³¹ in Tunis, Algers, and Tripoli, is B. berbera; and that in the Sudan B. aegyptica, and Borrelia hispanica is found in Spain and North Africa. Relapsing fever also occurs in India, and the causative microorganism is B. carteri. American relapsing fever is caused by still another spirochete, B. novyi; other strains isolated in this country have been named B. turicatae. South American strains have been called B. venezuelensis and B. neotropicalis.

All forms of relapsing fever are clinically identical. The onset is sudden, with chills, fever, and severe headache; muscular and joint pains are frequently observed, and there is a moderate enlargement and tenderness of the spleen and commonly jaundice. The fever ends suddenly by crisis in three or four days. Successive relapses occur at intervals of two to 14 days, and the period of relapse varies from a few hours to longer than the primary fever. The number of re-

lapses varies. Spirochetes may be found in the blood during the paroxysms. The case fatality is not high in European relapsing fever, perhaps 4 to 5 per cent. There are no characteristic findings at autopsy.

The infection may be transmitted to the rat and mouse, but the guinea pig appears resistant to most strains though it may be infected with certain American strains. Neonatal guinea pigs have been found to be more susceptible, and the susceptibility is differential with respect to at least some strains.11 It has been reported that the hamster may be infected with at least some strains. It is of some importance that the blood for inoculation be taken at the onset rather than at the decline of the relapse. Ordinarily the infection is inapparent in both rats and mice in that there are no observable symptoms, but successive "attacks," beginning two to four days after inoculation, are evidenced by the appearance of the spirochetes in the blood. They are present for two to three days, disappear, and reappear three or four days later in a second "attack." Usually only two or three such relapses occur, the spirochetes becoming fewer and persisting for shorter times in the successive relapses. Experimental disease may also be produced in monkeys, and its course is very similar to that in man. There is some evidence that tetracyclines may have utility as chemotherapeutic agents.

Natural infection of lower animals occurs

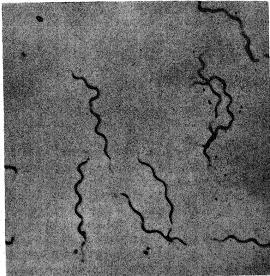

Figure 221. Relapsing fever spirochetes. Left, Borrelia duttonii of Central African relapsing fever; right, Borrelia kochii of East African relapsing fever. × 2000. (Kral.)

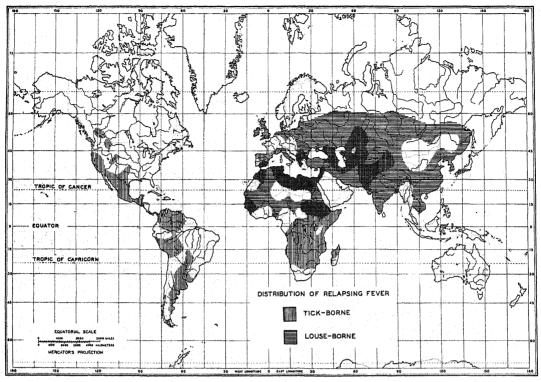

Figure 222. The world-wide distribution of relapsing fever, both louse- and tickborne. (Redrawn from map prepared by Army Medical Intelligence, 1943. Based on Goode Base Map No. 201 M. By permission of the University of Chicago Press.)

with some frequency in endemic areas, and there is much evidence to support the hypothesis that small mammals, especially rodents, constitute a natural reservoir of the tickborne infection. A wide variety of animals may be infected, including the rat, mouse, chipmunk, squirrel, opossum, porcupine, armadillo, hedgehog, fox, and dog. Susceptibility varies considerably among animal species, and from one strain to another of the spirochete.

A spirochetosis of geese is due to B. anserinum, a microorganism regarded by many as identical with B. gallinarum, which produces septicemia of chickens. Another species, B. theileri, is associated with a benign affection of cattle in South Africa but appears to have but low pathogenic powers. Morphologically similar spirochetes have also been found in the blood of sheep, horses, and bats and in the alimentary tract of fish and insects, but they are not associated with any obvious indisposition.

Immunity. Following infection, agglutinins and lytic and spirocheticidal antibodies may be found in the serum. Usually

the immunity following recovery from an attack of relapsing fever is of short duration, but occasionally a more solid immunity may develop. The latter is often attributed to a persistence of the infection, *i.e.*, an immunity to superinfection.

Relapse appears to be basically an immunological phenomenon and dependent upon the antigenic instability of the spirochete. It has been shown that the spirochetes will remain alive for as long as 40 days in blood drawn before the onset of an attack, but in blood drawn during the decline of an attack or after recovery they die out in less than an hour. In the latter case the blood is spirocheticidal and the killed spirochetes are phagocytosed. This has been taken to suggest that the relapse is a consequence of the survival of a few individuals which are resistant to the specific spirocheticidin and which multiply to give rise to a new serumfast strain. It has been found that spirochetes isolated after successive relapses differ serologically from the spirochetes of the first attack, and as many as nine different serological types of B. carteri were distinguished by Cunningham; after any particular type appeared in an animal it never reappeared in the further course of the disease in the same animal. It has been found that the two North American varieties, B. turicatae and B. parkeri, contain three antigenic components, A, B, and C, of which B is shared and invariant, while A and C are both strain and relapse-specific. Relapse serums are protective against both initial attack and relapse, whereas attack serum protects against attack but not relapse strains.

The parallel between this and the successive relapses of certain types of trypanosomiasis is striking (Chap. Thirty-four). In the guinea pig infected with Trypanosoma rhodesiense recovery is due to the development of a specific trypanolysin, the relapse to the multiplication of serum-fast trypanosomes, second recovery to a second specific trypanolysin, and so on. In this case the serum-fast strains are immunologically distinct from one another. In T. lewisi infections in the rat, however, both a trypanolysin and a reproduction-inhibiting antibody, or ablastin, are formed; the inhibition of cell division does not, presumably, allow the development of serum-fast strains, and hence there are no relapses.

Diagnosis. 15 The diagnosis of relapsing fever is made by demonstration of the spirochetes in the blood during the onset of a relapse by direct microscopic examination or by animal inoculation. Either the usual blood smear or a thick film similar to that used for the detection of malarial parasites may be used. The films are air-dried and stained with Giemsa; Wright's stain is satisfactory for thin films. The spirochetes may also be found in fresh wet preparations by darkfield examination. Mice and/or rats may be inoculated intraperitoneally and blood smears made daily for as long as two weeks if the spirochetes are not found.

Immunological methods of diagnosis have not been satisfactory in the past but Stein¹⁰¹ has prepared spirochete antigens by saponin hemolysis and washing of the spirochetes. Complement fixation, said to be preferable for diagnostic purposes, and agglutination with serums from infected persons or animals occur and are reported to be specific.

Epidemiology. The relapsing fever spirochetes are blood rather than tissue parasites, and the infection is transmitted by blood-

i delenar propinski propinski pravi se presed s

sucking insects, though rare cases of direct transmission may possibly occur. Two epidemiological types of the disease are to be distinguished, the one tickborne and representing transmission from an animal reservoir of infection to man, and the other louseborne and spread from man to man.⁹⁹

A tick vector was not recognized in this country until 1930, but the tickborne disease is now known to be not uncommon and at the present time is the only type which occurs. Known endemic foci of infection exist in Arizona, California, Colorado, Idaho, Kansas, New Mexico, Nevada, Oklahoma, Oregon, and Texas and possibly also in Montana, Utah, and Washington. Ornithodorus turicata and O. hermsi are known to transmit the disease, and it seems probable that O. parkeri transmits it also. but final proof is lacking. O. talaje transmits the infection in tropical America but apparently not in the United States; O. rudis is regarded as the most important vector in the tropics in this hemisphere. The traditional vector, and the most common in West Africa, is O. moubata. There appears to be no specific relationship between any particular species of tick and any particular strain of spirochete.

Infection may persist for long periods in the tick; Francis has reported survival in starved ticks for as long as five years, and in re-fed ticks for six and one-half years. In addition, the infection persists in the insect vector by transovarial transmission, under experimental circumstances to the fifth generation.⁴¹

The spirochetes are present in the coxal fluid, saliva, and feces of infected ticks. Of these, the first two appear to be the more important in transmission of the infection to man. For example, O. moubata, an excellent vector, secretes coxal fluid copiously while feeding, thus making possible infection of the bite, while O. hermsi, which is not known to transmit the infection to man though it does so from rat to rat, does not pass coxal fluid while feeding. The relative importance of direct introduction of the spirochete into the bite by infected saliva is not altogether clear. It is probable that infection of the bite by contaminated feces occurs occasionally.

European relapsing fever is transmitted from man to man by the human body louse, Pediculus vestimenti, and has the epidemiological characteristics of louseborne dis-

and the second second second second

ease. In contrast to the tickborne infection, the bite is not infected by the secretions of the lice; rather the infected louse must be crushed on the skin and the spirochetes present in the body fluids contaminate the bite. The infection is transmitted to the egg, and there is some evidence that the disease may be produced by crushed eggs laid by infected lice.

It is possible that the fingers may become contaminated by crushing infected lice and transmit the infection by scratching. The bedbug may also serve as a mechanical carrier of the infection.

Spirochetosis of fowls is transmitted by a tick, *Argas persicus*, which infects fowls in the warmer parts of the world, and, as in human relapsing fever, the spirochete is transmitted through the egg of the tick to the offspring.

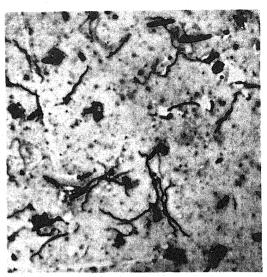

Figure 223. Smear from Vincent's angina showing the characteristic mixture of spirochetes (*Borrelia vincentii*) and fusiform bacilli. Fuchsin; × 1250. (P. E. Harrison.)

SPIROCHETES OF THE MOUTH

As described elsewhere (Chap. Twentyseven), spirochetes are a part of the normal flora of the mouth which, together with other microorganisms, may increase in numbers in ulcerative conditions of the mucous membranes and in peridontal disease. These forms are usually regarded as species of Treponema, viz., T. micordentium, etc. In the ulceromembranous stomatitis and angina known as Vincent's disease, Vincent's angina, or trench mouth, these forms. together with fusiform bacilli of the Bacteroides group, increase in numbers and predominate in stained smears from the necrotic lesion. Other bacteria, cocci, and bacilli are present also, and the typical microscopic picture is illustrated in the accompanying figure.

The spirochete found in such preparations is known as *B. vincentii* or *T. vincentii*, for the two genera cannot be separated on morphological grounds alone (see below). Whether this microorganism constitutes a distinct species of spirochete and plays any part in the development of the pathological process is questionable. It seems clear that the oral spirochetes are not pathogenic in the sense of being specific etiological agents of disease but, together with other microorganisms, may act synergistically in the accentuation, if not the initiation, of such suppurative infections.¹³

Treponema and the Treponematoses 47, 110, 117

Spirochetes of the genus Treponema are morphologically indistinguishable from Borrelia, but the pathogenic forms are set apart from the relapsing fever spirochetes by the kinds of diseases which they cause. The pathogenic forms are Treponema pallidum, the causative agent of syphilis; T. pertenue, the causative agent of yaws; T. carateum, the causative agent of pinta; and Treponema cuniculi, the causative agent of rabbit syphilis. T. microdentium and T. macrodentium are nonpathogenic, and a

part of the normal oral flora as indicated above, but are, in combination with fusiform bacilli, associated with ulcerative disease of the mouth, and this combination of microorganisms has also been found in certain types of tropical ulcer.¹⁰⁸

The pathogenic species of Treponema make up a group of interrelated microorganisms, separable by differences in the kinds of disease they produce. Conversely, the infections with these microorganisms, known collectively as the treponematoses,

are at the same time both similar, as with respect to the immune response, and differentiable by the character of the clinical disease. The treponematoses fall into three, or four, groups, viz., syphilis which is divided into the venereal and nonvenereal forms, yaws or tropical syphilis, and pinta or pintid yaws. The mode of transmission is thought by some to relate to differences in the diseases, i.e., the lack of systemic cardiovascular and neurological involvement in the nonvenereal forms.

The origin of treponemal infection has been a matter of absorbing and perennial interest. It is believed by some that an ancestral type of treponema, subjected to varying climatic, social, ethnological, economic, and other factors, may have differentiated into the several present forms of the microorganism, differing in their mode of transmission and in their pathogenicity with consequent variability in the human disease. 25, 51, 59, 60, 116

A disease similar to syphilis was present on the China coast in ancient times, the Biblical plague of Moab is thought to be syphilis, and syphilitic infection apparently occurred in Eastern Europe prior to the fifteenth century. Venereal syphilis, or morbus gallicus,58 occurred in epidemic form in Europe after the return of Columbus from the Americas, and it is believed by some that this form of treponematosis was introduced from the Western Hemisphere. There is evidence that syphilitic infection may persist in nonvenereal form following epidemics of venereal syphilis. The Scottish vaws or "sibbens" occurring in the seventeenth century after the time of Cromwell,70,82 "radesyge" in Norway, and "spirocolon" in Greece and Russia in the nineteenth century appear to be nonvenereal syphilis derived in this way. With improving economic and sociological conditions, the disease tends to die out-the last case of sibbens, for example, was reported more than 100 years ago – but it persists at the present time in the Near East, in Africa, and in Central Europe, and occurred in epidemic form in Chicago in 1949.

The earliest description of a yaws-like disease appeared in 1558 and occurred in Brazil, and the disease as known today was identified in the seventeenth century in the West Indies and in Brazil in the eighteenth century; it is now known to be ubiquitous in tropical regions. Pinta is more recently identified as a treponematosis occurring in

Mexico, Cuba, and adjacent areas; the spirochetal etiology was established in 1938 by Cuban workers on the basis of earlier studies by Herrejon; formerly it had been thought to be a fungous infection.

While the differences among these diseases are felt by some to require considering them as separate entities, the differences are not much greater than those between venereal syphilis in the Middle Ages and present-day venereal syphilis. It is believed by many that the similarities are more striking than the differences and these, together with other considerations, have led to a "unitarian" view of the treponemal infections in which the several clinical manifestations are considered to be variations on a central theme.

Cultivation. Schereschewsky reported the cultivation of T. pallidum in 1909, but his cultures appear to have been contaminated with other microorganisms. Noguchi later reported the growth of several strains of Treponema in pure culture under strictly anaerobic conditions in a serum water medium containing a piece of sterile fresh rabbit kidney or testicle. A number of such strains of spirochetes have been similarly isolated and may be grown in a heart infusion broth containing glycose, cysteine, and filtrate of coagulated plasma, the best known of which are the Reiter, Nichols, Kroo, and Kazan strains. In other instances the spirochetes may survive for extended periods, 113 but are not actually cultivated. The Reiter strain. although useful in serological studies, was originally virulent for rabbits when isolated by Wassermann and Ficker in 1922, later became completely avirulent but seems to have retained its antigenicity. The Nichols strain has retained virulence not only for the rabbit but also for man as shown by inoculation of human volunteers.73 In that study 57 spirochetes infected half of eight nonsyphilitic individuals, and the ID₅₀ for the rabbit was 23 spirochetes.

The Treponemas are extremely fragile microorganisms and die out quickly outside the body. They are destroyed by soap and water or by drying, and are unusually susceptible to heat; suspensions of infected rabbit testicle are sterilized at 41.5° C. in one hour and in two hours at 41° C., but the cultivable strains may remain viable in culture mediums kept at 37° C. for as long as a year. The viability of T. pallidum is of interest in connection with the possibility of transmission of syphilis by infected blood;

although occasional transmission has occurred in this way, the risk is not great with blood from blood banks, for the spirochete dies out in three or four days at refrigerator temperature and quite rapidly in lyophilized plasma.

Pathogenicity for animals. Syphilis may be transmitted to anthropoid apes, such as the chimpanzee and gibbon, and, with less certainty, to monkeys, as shown by Metchnikoff and Roux in 1903. Scarification of the genitals or eyebrows results in development of a primary chancre followed in a few weeks by the appearance of lesions of secondary syphilis.

Rabbits may be infected by inoculation of the anterior chamber of the eye. The local wound heals, but in four to six weeks pericorneal congestion develops which is followed by pannus and keratitis; then retrogression and healing occur. The entire process may take many weeks to complete. Intratesticular inoculation or implantation produces orchitis and intrascrotal inoculation a primary chancre; generalized lesions characteristic of secondary syphilis follow. A generalized infection may be produced by intravenous inoculation of very young rabbits. The spirochetes remain alive indefinitely in the lymphatics and may be obtained by excision of a popliteal gland. In rats and mice the infection is symptomless, but the spirochetes multiply in the tissues and the infection remains latent. Guinea pigs react similarly but may develop a local reaction following intracutaneous inoculation in the perineal fold.

The rabbit has been the experimental animal of choice, and the reaction to intradermal inoculation has allowed the differentiation of strains of Treponema with respect to pathogenicity. A small inoculum suffices to infect, and multiplication occurs exponentially after 24 to 48 hours, with the production of a mass of microorganisms and a visible lesion. With an inoculum of 500 spirochetes the incubation period is about 17 days; with an inoculum of 5000 microorganisms, four to five days, and the generation time is estimated to be about 30 hours.

In the initial stage hyaluronic acid is produced which appears to favor the multiplication of the microorganisms. In the second stage there is a mononuclear infiltration, and in the third stage an influx of polymorphonuclear leucocytes, and the infection may or may not involve the regional lymphatics.

elgi fiziki kiloni digeri (1946)

Three kinds of reaction in the rabbit, and also in the hamster, have been described by Turner and Hollander. 110 One of these, designated the Sh or syphilis type of reaction and given by T. pallidum from venereal syphilis, consists of an indurated lesion at the site of inoculation and lymphatic involvement. Samoan strains of T. pertenue produced only minimal local reaction and no infection of the lymphatics, designated the Yh reaction. An intermediate reaction, the Mh type, with pronounced local lesion and lymphatic infection, is given by some yaws strains and by spirochete strains from nonvenereal or endemic syphilis. Although it has been reported⁶⁹ that the rabbit may be infected with T. carateum, the infection has not been fitted into these types.

Immunity. The immune response in treponematosis is two-fold. The antibody-like activity designated reagin has wide diagnostic utility (see below), characteristically reacts in complement fixation and flocculation tests with nonspecific cardiolipid prepared from normal tissues, and its titer is correlated with the status of the clinical disease, disappearing when cure by chemotherapy is effected. The other is an antibody response to antigens present in the spirochetes, demonstrable with spirochetal antigens as immobilization and other phenomena (see below). It is generally believed that there are three kinds of antigens present in the spirochetes, a thermolabile protein antigen, a thermostable polysaccharide antigen, and a lipoidal antigen similar to the material present in cardiolipin preparations. There appears, however, to be no immunological difference between the spirochetes of venereal syphilis, nonvenereal syphilis, yaws, and pinta, and all of these diseases give positive reactions to the same serodiagnostic tests. It has been reported³⁴ that T. pallidum shares a common antigen, the Reiter protein antigen, with the Reiter treponeme, T. microdentium, and T. zuelzerae, but by the use of absorption or blocking procedures and application of fluorescent antibody methods, they may be differentiated from one another.

TREPONEMA PALLIDUM (Syphilis)

Syphilis, by far the most intensively studied of the treponematoses, occurs, as

indicated above, in two forms. One is venereal syphilis and is the best known form, and the other is nonvenereal or endemic syphilis. The two are epidemiologically distinct in that transmission is almost always sexual in the first instance, but in the second the infection is transmitted both by direct nonsexual contact and indirectly by the common use of eating and drinking utensils among children and adolescents. Consistent with this, the primary lesion is usually on the genitalia in venereal syphilis, but the first lesion occurs as oral mucous patches in the childhood disease.

The prevalence of syphilis is not known definitely; the estimate that 10 per cent of adults in the United States will give positive Wassermann tests is probably fairly accurate. It is also estimated that between 1 and 2 per cent of the children in this country have congenital syphilis. The mortality from syphilis is also not known. The death rate of 13 to 14 per 100,000 is misleading, for deaths reported as due to other causes are frequently due to syphilis; all cases of general paresis, locomotor ataxia, and many cases of apoplexy and aortic aneurysm are, for example, due to syphilitic infection, and the disease is a contributory cause in deaths from other diseases. Studies on the incidence of syphilis in autopsies on adults have given rates of from 2.6 per cent to 29.5 per cent; the average in 146,761 autopsies performed from 1896 to 1938 was 5.45 per cent. In this

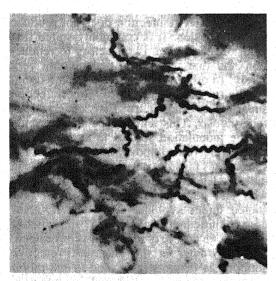

Figure 224. Treponema pallidum in stained (silver impregnation) smear. × 3000. (Kral.)

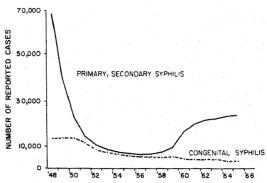

Figure 225. The prevalence of syphilis as indicated by reported civilian cases in the United States during the period 1948–1965. (Morbidity and Mortality Weekly Report, Annual Supplement, Vol. 14, No. 53. Communicable Disease Center, Public Health Service, U.S. Department of Health, Education, and Welfare.)

country the prevalence is much higher in the Negro than in the white; tests of the first two million selectees under the Selective Service Act showed 2 per cent in whites and 22 per cent in Negroes. There is considerable variation in the ratio from one part of the country to another.

The number of reported cases continued to fall in this country until 1955, remained steady until 1958, then increased from 113,894 in that year to a peak of 126,245 in 1962, and has since declined to 112,842 in 1965. Such data are only relative, for many cases of syphilis are not reported. It is estimated that the reservoir of untreated syphilis cases is 1,200,000, and that the annual increase is about 60,000. There are currently about 33,000 paretics in institutions. ¹⁸

The disease in man. A disease of protean manifestations, syphilis in man assumes several relatively well-defined clinical stages. The ordinary course of the disease includes the successive appearance of the so-called primary, secondary, and tertiary stages; congenital syphilis is best regarded as a separate subdivision.

Primary stage. Following the penetration of the skin or mucous membranes, the spirochetes rapidly invade the tissues; it has been found that the inguinal lymphatics of rabbits become infective 30 minutes after cutaneous inoculation of the scrotum. The initial primary lesion appears 10 to 30 days following infection. The typical hunterian chancre (so-called because it was described accurately and in detail by John Hunter) is an indolent, indurated ulcer, single and painless, and not

infrequently atypical and trifling in appearance. The presence of the spirochetes in the chancre serum may be demonstrated by darkflield examination and constitutes the diagnostic method in early primary syphilis, for a positive Wassermann reaction (see below) does not develop until two or three weeks after infection. Clinically, then, syphilis in the primary stage is a localized infection, but bacteriologically it is a generalized infection, and spirochetes are often present in the blood stream.

Secondary stage. In the secondary stage the generalized nature of the infection is apparent. Bones, joints, eyes, and other organs are invaded, with the appearance of constitutional symptoms, cutaneous lesions, enlargement of the lymph glands, pains in the joints, and the like. Evidences of the development of this secondary stage are usually apparent four to eight weeks after the appearance of the chancre but may be delayed for a year or more. Spirochetes are present in all the lesions and may be found in the blood stream.

Tertiary stage. The disease passes insensibly into the tertiary stage and may persist for years. Ulcerating necrotic lesions of the skin and gummata of the internal organs are common, and the clinical manifestations of infection are so highly diverse that there is no characteristic picture. Spirochetes are present in the tertiary lesions but only in small numbers.

Neurosyphilis. Spirochetal invasions of the central nervous system may occur independently of the so-called stages and as soon as the early secondary stage. Generally, however, neurosyphilis is a manifestation of late tertiary infection and may appear years after the initial infection, and tabes dorsalis, general paresis, and other evidences of the invasion are sometimes termed quaternary or parasyphilitic affections. The spirochetes may be found in the cord in tabes dorsalis and in syphilitic brains in the cortex, in the pia and vessel sheaths. General paresis is, then, a diffuse spirochetosis of the brain involving the cortical layers chiefly, and the presence of the spirochetes in the parenchyma explains much of the histopathological picture and the nervous symptoms of the affection.

Latent syphilis.²⁸ In some instances the primary lesion is not noticed and the secondary manifestations may be slight, and with their subsidence there is no clinical evidence

of disease and the infection remains latent within the tissues. In other instances the latent condition develops after primary and secondary symptoms of usual severity. Such clinically latent infections may, perhaps, be regarded as the maintenance of a biological balance between the host and the parasite. Latent infections may, of course, develop clinical manifestations at a later time.

Congenital syphilis. The fetus is readily infected in utero by spirochetes passing through the placenta. The infection may result in a cessation of development and abortion, or the fetus may go to term and be born dead. In those who survive, the disease is generalized from the beginning, and the lesions are those of tertiary syphilis. Spirochetes may be demonstrated in great numbers in the tissues and organs affected. Third generation syphilis has been reported but is very rare. 93

Immunity. 19, 115 At the present time syphilis is not so severe a disease in man as it was in the early sixteenth centry. Whether this is an expression of an adaptive response on the part of man with the development of a low degree of natural immunity, or a similar response on the part of the parasite manifested as a decrease in virulence, is not known; possibly both may have occurred.

The specific immune response to syphilitic infection is not well understood. There is a marked apparent insusceptibility to reinfection that is illustrated by the fact that a second chancre may be produced by reinfection prior to the appearance of the first chancre, but after the first chancre has appeared further reinfection does not produce an initial lesion. It is commonly stated that man, once infected, is refractory to reinfection and that reinfection occurs only very rarely. In other words, there is an infectionimmunity or immunity to superinfection superficially similar to that observed in tuberculosis. This tends to be substantiated by the inoculation studies in human volunteers⁷³ referred to above, in which 100,000 spirochetes failed to infect individuals having untreated latent syphilis, 10 of 26 persons who had been treated for proved or presumed latent syphilis, while the ID₅₀ for nonsyphilitic individuals was 57 spirochetes.

A certain degree of immunity is developed, especially later in the disease. Protective antibody is demonstrable, and in the rabbit a partial immunity, produced by infection and cure with penicillin after varying times,

inhibits to a certain extent dissemination of infection following subsequent inoculation. In addition, the spirochetes are immobilized and killed in syphilitic serum in the presence of complement. An *in vitro* immobilization test has been devised for the demonstration of this activity (see below), but it is not clear to what extent it is associated with effective immunity.

Serodiagnosis.¹⁰⁴ As indicated above, the immune response is of two kinds, the appearance of Wassermann antibody, or reagin, and of antibody to antigenic substances present in the spirochete. The former has been widely used for diagnostic purposes, while the latter response is immunologically specific, but its assay is as yet too complex for general application.

A complement fixation test was proposed by Wassermann and his co-workers in 1906 as an immunologically specific reaction, using a watery extract of syphilitic fetus as the antigen. It was soon found, however, that syphilitic serums fix complement in the presence of an extract of normal tissue.

Not long after the development of the Wassermann test it was observed that syphilitic serums produce a flocculation when mixed with Wassermann antigen. The reacting substance present in the antigen preparations occurs in various tissues, but heart (beef) muscle extracts are the most satisfactory. It is soluble in alcohol and insoluble in acetone, and its activity is considerably increased by the addition of cholesterol. Activity of these extracts is due to a phospholipid, cardiolipin, which is precipitated from the initial alcoholic extract with cadmium chloride, freed from lecithin, and fractionated by precipitation from ether with acetone and alcohol. Anticomplementary activity of the preparation is removed by the addition of lecithin,68 and complement is not fixed unless cholesterol is added. The function of lecithin is not clear, and it may function only as an emulsifying agent. The complete lecithin structure seems to be required, and dimvristovl lecithin may be substituted for natural lecithin.3 According to Pangborn, 80 who described this substance in 1941, it is a complex phosphatidic acid. A similar product of vegetable origin (wheat germ) sitolipin, has been prepared. The activity appears to be a property of similar substances varying in their fatty acids; lauric and linoleic acids have been found to be present, together with a third component.90

Types of tests. Probably no serological reactions have been as intensively studied as the complement fixation and precipitation tests for syphilis, and the techniques have been modified and refined by many workers to increase sensitivity and specificity. At the present time two complement fixation tests, the Kolmer test and the Venereal Disease Research Laboratory (VDRL) test, and four precipitation tests, the Kahn test, the Kline test, the Hinton test, and the Eagle precipitation test, are used. In addition to these. more sensitive precipitation tests have been devised by Kahn and by Kline and are known as the Kahn presumptive test and the Kline exclusion test: they are apt to give false positive reactions but are regarded by some workers as having considerable utility as screening tests. A rapid unheated serum reagin, USR, is used also for presumptive purposes.114

The complement fixation test may also be quantitative; *i.e.*, the reagin present in the syphilitic serum may be titrated. For ordinary diagnosis this is unimportant since it is not known whether the reagin titer has any significance, but it is useful in following therapy and in the diagnosis of congenital syphilis in infants. In the latter case reagin is passively transferred from the maternal circulation; if the infant is not infected the reagin titer drops slowly, but a gradually increasing titer is indicative of infection.

Specific tests. Any serological test making use of spirochetal antigen, and thus having immunological specificity in the conventional sense, should be much more precise. An antigen may be prepared from T. pallidum by making an extract of infected rabbit testicular tissue with citrate, acetone, and deoxycholate for use in the T. pallidum complement-fixation, or TPCF, test.⁷² The antigen may also be obtained by differential centrifugation of T. pallidum from infected rabbit tissue, cryolysis, and ammonium sulfate precipitation to give the T. pallidum cryolysis complement fixation, or TPCP, test. The cultivable Reiter strain contains antigens in common with T. pallidum as demonstrable by absorption tests and may also be used as a source of antigen in the Kolmer-Reiter protein complement fixation. or KRP, test.44

The treponema immobilization test (TPI), in which the living motile spirochetes are specifically immobilized in the presence of antibody, complement, and thioglycollate

(the last to maintain anaerobic conditions), has been devised. It has been widely and critically tested and found to be highly specific. 16 As originally carried out, it required 18 hours, but it has been found that the addition of egg white lysozyme reduces the required time to six hours. 77 The fluorescent antibody technique has also been applied to the serodiagnosis of syphilis, using both the direct and indirect methods 32, 33 to give a fluorescent treponemal antibody, or FTA, test. The test is highly sensitive and correlates well with other serological methods. 39, 79

The wide variety of serodiagnostic tests is an expression of a continuing search for a completely reliable test, but it is probable that no single test will suffice in the face of complications of therapy, biological false positives and negatives, etc. Some combination of tests may be required as indicated by circumstances (see below); one such combination which has been suggested²⁰ is that of the VDRL slide test, the RPCF test, and the TPI test.

The effect of therapy. The majority of individuals undergoing therapy become serologically negative to the cardiolipin type of test in time, and this response is usually taken as an indication of the efficacy of the treatment. The time required to attain negativity is variable and depends upon the individual, the stage of the disease, the course of therapy, especially if continuous or intermittent, and the sensitivity of the serological test used. No general statement of any precision is possible, therefore, but it is usually said that the majority of persons with primary or early secondary syphilis become negative after one or two courses of arsenical or continuous treatment for five to seven weeks. Some, however, become negative with only one or two injections of drug, while others may remain positive for months, and a certain proportion remain positive indefinitely. The last is spoken of as Wassermannfast, reagin-fast, or seroresistant syphilis.55 Slightly over 10 per cent of infections are in this group. Two explanations are usually offered for seroresistant syphilis, one that persistent foci of infection remain, and the other that the continued presence of reagin is evidence of a definite immune response.

Specificity and false reactions. False negative reactions are in part a technical matter; serological tests in general use give 80 to 90 per cent positive reactions with known serums, and any test which gives more than

80 per cent positives is regarded as satisfactory. The presence of insufficient reagin accounts for many false negative reactions and occurs in several stages of the disease. especially in early primary syphilis (a positive reaction usually does not develop until two to three weeks after infection) and late syphilis which is latent or localized. Tabes, for example, gives about 40 per cent negative reactions. Negative reactions may also be a result of the presence of antibody to the Forssman antigen, acquired for example by prior infection with microorganisms containing the antigen, such as certain strains of pneumococci, in the serum tested. If such antibody is present to reasonably high titer. the sheep cells of the indicator system are lysed in the presence of complement. This may be avoided by a preliminary absorption of the serum with sheep cells.

False positive reactions may be a result of technical error or may be biological in nature. A certain proportion of nonsyphilitic individuals suffering from other infections give positive serological tests for syphilis. All cases of yaws are Wassermann-positive, and it is reported that 4 to 10 per cent of cases of malaria are positive. Brucella infection has also been reported²¹ to be associated with false positive reactions. Febrile disease of one sort or another occasionally produces isolated or repeated positive reactions. Biological false positive reactions to the cardiolipin tests are thought to be often associated with collagen disease.⁶³

False reactions occur less commonly with the specific tests using treponema or treponemal antigen, and these have their greatest utility when the more readily performed slide precipitation and other kinds of nonspecific reactions give equivocal results.^{24, 40} The treponemal tests are subject to error also, but these may be technical in nature.⁹⁴

The nature of the response to infection with the spirochete that results in the appearance of reagin is not clear. Et lack of immunological specificity would seem to rule out the usual type of antibody response, but if it is to be regarded as antibody, the facile disappearance of reagin during therapy rather than seroresistant syphilis requires explanation. It is possible that reagin represents iso-antibody that is detectable only because it is being produced more rapidly than it can be removed by union with antigen.

Chemotherapy. The chemotherapy of syphilis, like that of tuberculosis, has been

of great interest for many years. The long-term treatment with arsenicals and bismuth was highly effective for the relatively small number of patients who did not default. For example, of 1340 cases treated over a period of four years and followed for an average of 11 years, there were only nine failures of which four were reinfections. This method of treatment is now a thing of the past although arsenicals and/or bismuth have been used in combination with penicillin. 23, 61

Of the chemotherapeutic drugs now available, the sulfonamides are ineffective, but penicillin has been found to be highly effective. For example, in the research series of the U. S. Public Health Service, 1538 patients treated on various schedules were followed for two years. In this group 92.3 per cent of those having intially seronegative primary syphilis, 82.4 per cent of those with seropositive primary syphilis, and 78.3 per cent of those with secondary syphilis were cured. The relative efficiency of penicillin therapy and the adjuncts made use of are dependent upon the stage and nature of the disease.²⁹

The broad-spectrum antibiotics, chloramphenicol, and the tetracyclines are apparently almost as effective as penicillin in the chemotherapy of syphilis. As yet only relatively small numbers of patients have been treated with them, and their ultimate value can be determined only by studies carried out with large numbers of patients over a period of years. While as yet the incidence of penicillin-resistant spirochetes has not assumed practical importance, the occasional occurrence of penicillin-resistant strains coupled with individual sensitivity to this drug is indicative of the utility of alternative chemotherapeutic agents.

NONVENEREAL SYPHILIS

Nonvenereal or endemic syphilis occurs in foci in many parts of the world under various local names. That occurring among the desert Arabs in the Near East is known as bejel,⁵⁷ that in Karanga people in southern Rhodesia is njovera, dichuchwa is the disease found among the Bantus in Bechuanaland,⁷⁶ and the disease is known locally as siti in Gambia. It occurs in southeast Asia and with some frequency in eastern Europe, especially in Bosnia in Yugoslavia.⁴⁵ In the last area, prior to mass treatment under WHO auspices, patients with the disease

made up as much as 5 per cent of the population.

The disease is an epidemiological rather than clinical entity, occurring, as indicated earlier, largely in children and within families. There appears to be little or no basis for separating the diseases occurring in widely separated foci from one another or from venereal syphilis. Clinical differences between venereal and nonvenereal syphilis, viz., the relative rarity of primary lesions and congenital manifestations in the latter, seem to be a consequence of the mode of transmission and age distribution of the disease rather than of differences in the pathogenicity of the causative microorganism. There is, however, some uncertainty as to the frequency of cardiovascular and neurological involvement; it seems to be relatively rare, but not unknown, in nonvenereal syphilis, but the nonvenereal form of the disease may occur mixed with venereal syphilis.

The first manifestations of the infection are most commonly mucous patches in the mouth, and skin lesions including anogenital condylomata occur also. These lesions show the presence of spirochetes on darkfield examination, as do the lesions found on the nipples of mothers infected by children. In most individuals latency occurs after the early stages, with subsequent development of tegumentary lesions, including gummatous destruction of the skeleton, which are indistinguishable from those of venereal syphilis. The causative microorganism is *T. pallidum*, and the disease is effectively treated with repository penicillin.

TREPONEMA PERTENUE (Yaws)87, 103

Yaws, or frambesia tropica, is a disease occurring in tropical countries and is common in Equatorial Africa, the tropical regions of the Far East though rare in India, the West Indies, and tropical America. The incidence may be high, 5 to 20 per cent, and the disease is a major public health problem in Haiti. It is prevalent in rural rather than urban areas and associated with low economic status, i.e., the wearing of clothing appears to protect. Primary infection is more common in children than in adults. The causative agent is T. pertenue, which was described by Castellani in 1905.

The spirochete is found in the serous ex-

udate of the cutaneous lesions and in the lymphatics. It may be demonstrated in Giemsa-stained smears or by darkfield examination of fresh preparations and is morphologically indistinguishable from *T. pallidum*.

The disease in man49 is characterized by a papular eruption. The commonest site of infection, perhaps in 75 per cent, is the lower leg and foot. A general malaise precedes the appearance of the initial lesion, which is practically always extragenital and takes the form of a single papule or a small group of them. The papule enlarges to a diameter of 3 to 4 mm., the thickened epidermis cracks, and the fungoid mass beneath exudes a seropurulent fluid. The mass enlarges to 3 to 5 cm. in diameter and the lesion is termed a yaw. When the infection occurs on the sole of the foot, it is known as crab vaws or wet crab yaws. It eventually dries, leaving only a scar. Six weeks to three months after the primary lesion appears, a secondary eruption occurs which is similarly preceded by a general malaise. The lesions are of the same general character as the primary lesion, appearing on the extremities, neck, and at the juncture of the skin and mucous membrane about the nose, mouth, and anus. Tertiary lesions similar to those of syphilis are said to be rare, but recent work suggests that they may be more common than has been supposed. The Wassermann reaction is positive, and in certain stages, as in late secondary eruption, differential diagnosis may be very difficult.⁵²

Yaws may be produced by inoculation in monkeys and rabbits. The infection in rabbits with *T. pertenue* is similar to that with *T. pallidum*, but relatively few spirochetes are found in the lesions, multiplication is arrested early, and the inflammatory reaction is slight.

The disease is seldom venereal, and the commonest mode of transmission is contact between individuals.^{48,50} Trauma of the skin usually precedes infection, and the ability of the spirochete to penetrate the intact skin is questionable. Biting flies may also transmit the disease, and in Jamaica the small fly, *Hippelates pallipes*, feeds upon the serous exudate in huge numbers, the

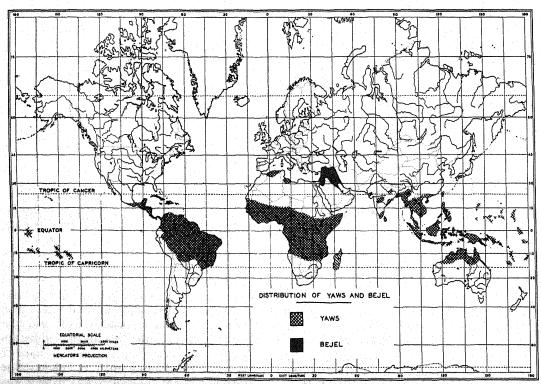

Figure 226. The world-wide distribution of yaws and bejel. (Redrawn from map prepared by Army Medical Intelligence. Based on Goode Base Map No. 201M. By permission of the University of Chicago Press.)

spirochete surviving for some hours in the diverticulum of the fly and possibly being regurgitated when the fly feeds upon a skin abrasion.

Yaws may be successfully treated with penicillin, and there is evidence that chloramphenical and tetracyclines may also be effective. The change to seronegativity is usually not as rapid as in effectively treated syphilis, possibly because the disease is usually of longer standing.

The relationship of yaws to syphilis is very close, the points of difference being the nonvenereal transmission of yaws, the differences between the yaw and the indurated hunterian chancre, and the relative infrequency of visceral and tertiary lesions. Yaws is regarded by many as a tropical type of syphilis, differing, not necessarily qualitatively, from endemic syphilis as a result of environmental factors. There is some evidence of a cross-immunity between syphilis and yaws in that the two diseases tend to be mutually exclusive, but precise evidence is lacking.

TREPONEMA CARATEUM (Pinta)^{22, 56, 74}

Pinta, known in Mexico as mal de pinto and in Colombia as carate, is clinically a skin disease in which dyschromic changes occur in patches which may be discrete and small or large and confluent, and of a gray, bluish gray, or pinkish color and eventually white. It is especially prevalent in Mexico, where 11 per cent of over two million persons examined had the disease, and in Colombia, where as much as 4 per cent of the population in some districts are affected. It also occurs in Cuba and the West Indian Islands and in Central America and tropical South America. There is some question as to whether the Mexican and Cuban diseases are identical.¹¹¹ It is apparently confined to the Western Hemisphere for the most part, but cases have been reported from India.42

Etiology. For many years this disease has been of uncertain etiology though generally assumed to be a fungous infection. It was suggested by Herrejon in 1927 that the disease is caused by a spirochete, but it was not until 1938 that a spirochete was first demonstrated by Armenteros and Triana in Cuba. The observation has been amply con-

firmed, and it is now established that pinta is caused by a spirochete which has been named *T. herrejoni* by the Cuban workers and *T. carateum* by Brumpt.

The spirochete may be found in material taken from early cutaneous lesions and in that aspirated from lymph glands. It stains with Giemsa and by the usual silver impregnation methods used for T. pallidum and may be found by darkfield examination of fresh material. Morphologically it is very similar to, perhaps indistinguishable from, the spirochete of syphilis. While it gives no cross-reaction with T. pallidum in the immobilization test, the pattern of the universal serological reaction of Kahn is identical with that of syphilis. Attempts to cultivate it have failed, but it has been reported that the rabbit may be infected. The experimental disease in human volunteers has been studied in considerable detail, however, especially by Leon y Blanco.

The disease in man. In the experimental infection the incubation period is from seven to 20 days, with the initial lesion being a papule which appears at the site of inoculation. This papule spreads peripherally to form a squamous, erythematous patch reaching a diameter of 1 cm. in four or five weeks. It continues to spread, varying considerably in appearance, and may be lichenoid or psoriaform. There is less inflammatory reaction than in either syphilis or yaws.⁵³ Leon regards this as the primary stage. In about five months the secondary stage begins with the appearance of secondary lesions about the initial lesions and elsewhere on the body. Progressive hyperpigmentation occurs, and depigmentation, resulting in varied hues, follows in the third stage; keratosis and superficial atrophoderma become apparent. Hyperkeratosis on the plantar surfaces occurs in Cuba but is seldom observed in Mexico. The Wassermann reaction is almost always negative in the primary stage, positive in something over half the cases in the secondary stage, and practically always positive in the tertiary stage. Correspondingly, superinfection is readily produced in the first stage but not in the third stage. Syphilitic individuals may be infected without difficulty. Pinta may be successfully treated with penicillin.

Transmission. 98 Experimental human infections have shown that serous fluid from the early lesion is highly infectious when placed on an abraded area on the skin, and

CONTRACTOR STATE OF THE PARTY O

the spirochete may be demonstrated in the discharge from the fissures in plantar hyperkeratosis. Contact infection would appear to be possible, but general opinion is that it is not an important method of spread. Simulium flies have been suspected of transmitting the disease, but as yet an insect vector has not been demonstrated.

Leptospira and Leptospirosis 4, 5, 105

Leptospirosis, or infection with leptospira, is a not uncommon and widely distributed affection. Several species of leptospira are involved, and the infections differ somewhat in their clinical manifestations.

Morphology. The leptospiras differ from Treponema and Borrelia species in that their spirals are very fine and close, one or both ends of the cell may be hooked, and the individual cells are smaller, not more than 0.3 μ in breadth and generally 6 to 10 μ in length, although exceptionally forms as long as 25 to 30 μ may be observed. The protoplasm is spirally wound about a delicate but firm. elastic, smooth axial filament enclosed within a well-defined cell wall, which is clearly shown in electron micrographs. 91, 97 Like the finer bacterial flagella, the axial filament is not seen in the darkfield or ordinary stained preparations but may be demonstrated by silver impregnation flagella stains. The

periplast is thick and almost transparent and appears in the darkfield as a narrow, clear zone or halo and in certain stained preparations as a grayish or unstained halo. The mechanism of locomotion is more complex than in the treponemas; the hooked ends of the axial filament are probably involved, and when the bow-like axial filament is alternately straightened and relaxed by rhythmic contractions of the protoplasmic spirals the cell rotates. Their small breadth and active motility allows penetration of filters such as the Berkefeld V and N candles, and filtration is often used on primary isolation from contaminated materials to separate them from other bacteria.

Cultivation. 66 The leptospiras are the most readily cultivable of the spirochetes. They may be grown in a liquid medium consisting of 1 per cent peptone in phosphate-buffered Ringer solution to which sterile

LEPTOSPIRA 761

rabbit serum is added in a final dilution of 1:40, or in a semisolid medium consisting of meat extract agar enriched by the addition of sterile serum. In the isolation of leptospira from the blood, the inoculum is in the proportion of 0.03 ml. of blood to 15 ml. of medium, and the culture is incubated for as long as 28 days before discarding. The blood presumably satisfies the nutritive requirement for iron. One of the most readily prepared liquid mediums for the cultivation of leptospiras is that described by Cox.26 consisting of 0.2 per cent tryptose-phosphate broth enriched by the addition of normal rabbit serum to 10 per cent. Some strains have been grown in chemically defined mediums. 100, 112 In the isolation of leptospira from water, agar medium and blood may be added to Berkefeld V and N filtrates. The leptospiras are all obligate aerobes. Those tested do not ferment sugars and are indifferent to the presence of carbohydrates in the medium.

Colonial growth of leptospiras on solid medium has been described by Cox and Larson²⁷ on tryptose-phosphate-normal rabbit serum medium enriched with rabbit hemoglobin and solidified with 1 per cent agar. Two types of colonies were observed, a small relatively opaque type and a larger translucent form ranging in size from 1 to 4 mm, in diameter.

Cultures are maintained in liquid or soft agar medium which may be covered with a thin layer of paraffin oil to retard evaporation. The cultures are incubated at 28° to 30° C. for one to two weeks, during which leptospiral growth appears as a band of turbidity a few mm. below the surface. Such cultures remain viable for five to six months when stored at room temperature, and should be transferred as 0.5 ml. of inoculum every three to four months. For serological purposes the cultures should be young, one to three weeks old. It has been reported that leptospira may remain viable when stored in dry form at refrigerator temperatures.

Antigenic structure. 10, 89 The leptospiras are excellent antigens, and agglutinating, lytic, and complement-fixing antibody is produced to high titer and persists in the case of recovered individuals, man or lower animal, to allow diagnosis of past infection. The several species or types of leptospira are differentiable and characterized on an immunological basis, and many serotypes have been established, with new serotypes being added from time to time.

The serotypes have been given place or descriptive names, implying that they are different species, but no formal classification within this group is firmly established. It has been tentatively suggested⁸⁸ that only two valid species be recognized, *Lept. interrogans*, including the parasitic forms, and *Lept. biflexa*, the saprophytic strains, with no taxonomic status for sertotypes or groups of serotypes. A collection of serotypes is maintained at Amsterdam in Europe and at the Walter Reed Army Medical Center in this country.

These serotypes appear to be quite stable although antigenic changes can be produced by cultivation in antiserum.⁸¹ There are minor cross-reactions with some other microorganisms, including Shigella strains.⁹² Immunity to experimental infection is largely type-specific with only occasional cross-protection between serotypes.

Pathogenicity. The pathogenic leptospiras are parasites of lower animals, including wild rodents and a variety of domestic animals of which the pig and dog, and in some areas cattle, are probably the most important quantitatively. Unlike Borrelia, they are not primarily blood parasites although they may be found in the blood as early as the first day and perhaps as late as the fourteenth day of the disease. The infection localizes in the tissues and organs, especially the kidneys, and the leptospiras are excreted in the urine.

Human infection is acquired from lower animals, by direct contact with infectious urine or water contaminated with infected urine or by direct contact with infected tissue. In the first instance the source of infection is most often rodents, and the leptospira penetrate the skin, and in the second, domestic animals, especially pigs, which serve as a source of infection for slaughterhouse workers, veterinarians, and herdsmen, as in swineherd's disease in Switzerland.

Leptospiral infections in man are all closely similar and are characterized by a febrile reaction, jaundice which may be generalized or confined to the sclera, and infection of the kidneys.^{7,8} Weil's disease, or infectious jaundice, is the classic example of leptospirosis and has been known for many years (see below).

Other infections with leptospiras are much more common than has been realized. In many instances these are acquired through contact with mice and other infected rodents, and, since the infection often occurs in connection with working in cultivated fields and similar rural areas, the disease is variously known as swamp fever, field fever, harvest fever, and the like. Such leptospirosis is given place names also, such as Mossman fever and Pomona fever, but in many, if not most, cases infection is much more widespread than this would suggest. The etiology of these diseases is nonspecific in that there is little specific association of a give disease with leptospiral serotype.

Recovery from the disease is accompanied

by the appearance of specific antibody and the development of an effective immunity. Prophylactic inoculation with leptospiral vaccines has been applied, with encouraging results, to groups of persons exposed to infection.⁹

Laboratory diagnosis. 86, 118 The laboratory diagnosis of leptospirosis is based upon isolation of the infecting microorganisms and on the immune response to the infection. In man the bacteria may be isolated from the

blood early in the disease by culture or animal inoculation; for the latter, young (150 gm.) guinea pigs or weanling (15 gm.) hamsters are the usual animals. The experimental infection may be substantiated by demonstration of the leptospira in the tissues, especially in the kidney, on culture at autopsy, but in general animal inoculation gives a smaller proportion of positive results than does culture.

The immune response may be assayed as leptospiral agglutination (observed in the darkfield microscope), as lysis in the presence of complement, or by complement fixation. The agglutination-lysis titers range from 1:400 to 1:100,000, and the complement-fixation titers from 1:32 to 1:256. A four-fold or greater rise in antibody titer in paired serums is regarded as diagnostic, but in an appreciable portion of cases (10 per cent?) demonstrable antibody is not present. The immune response in infection is ordinarily of sufficiently broad specificity that the serological identity of the infecting microorganism is not deducible from it, and for precise identification the leptospira must be cultured and typed serologically.

Chemotherapy. Penicillin, tetracyclines, and erythromycin are somewhat effective in the early stages of experimental infections, and the last two, and streptomycin, may have some effect on the kidney infection. Chloramphenicol seems to have little or no value. In general, chemotherapy of human infections has been disappointing.

WEIL'S DISEASE (Infectious Jaundice)

The causative agent of Weil's disease, Leptospira icterohemorrhagiae, was discovered in 1914 by Inada and Ito in Japan and was found in Germany the following year by Hübener and Reiter and by Uhlenhuth and Fromme. It was called Spirochaeta icterogenes by the German workers. The disease has been found all over the world; it is very common in Japan, less so in Europe, where the greatest incidence is in the Netherlands and France, and is not uncommon in South America. It is probably not so rare in the United States as has been supposed.

Disease in man. The incubation period is six to 12 days, and the high initial fever is followed by nausea and vomiting, epi-

staxis, headache, and muscular pains, and there may be moderately severe bronchitis. Jaundice is not always observed; it occurred in 40 to 60 per cent of the Dutch cases. Convalescence is slow, and weakness may persist for months.

The leptospira are distributed throughout the body in the first week of illness and may be demonstrated in the blood by guinea pig inoculation but rarely in blood smears. After the first week they are present in the urine and may continue to be so excreted for four to five weeks. There is some evidence that the case fatality is reduced by treatment with antiserum. In fatal cases death usually occurs during the second or third week, but occasionally as early as the end of the first week. The case fatality is variable; it has varied from 4.6 to 32 per cent in Japan and has been about 10 per cent in the Dutch cases and as high as 25 per cent in Scotland. At autopsy the leptospira are found in almost all the organs and tissues in those dying during the initial febrile stage, but if death occurs in the second week or later, they are rarely found elsewhere than in the kidneys. Acute renal failure is the commonest immediate cause of death.

Immunity. Recovery from the disease is accompanied by the development of a solid immunity, and a specific lysin is present in the blood which persists in detectable amounts for several years. Agglutinins appear in the convalescent stage, sometimes to very high titer, but the relation of demonstrable antibody and effective immunity is far from clear. Prophylactic inoculation has given encouraging results.

Transmission. The wild rat is the most important animal reservoir of infection, and Schüffner has reported that 40 per cent of tame rats raised for experimental purposes have been found to be infected in Holland. The infection may be detected by darkfield examination of urine and kidney emulsion, and preferably by the inoculation of young guinea pigs with kidney emulsion. Larson has found that a fatal infection may be produced in young mice three to four weeks old.

The proportion of infected rats is variable from one locality to another; in New York about 4 per cent of the rats have been found to be infected, in Japan 40 per cent, in England 30 per cent, in Rotterdam 7 to 40 per cent, and in Philadelphia about 10

per cent. The leptospira are discharged in the urine of infected rats and are transmitted to man via stagnant water contaminated with rat urine. Weil's disease is to some extent an occupational disease and occurs in coal miners, sewer workers, and other working in contact with contaminated water. The majority of the Dutch cases have been in swimmers, bargemen, and fishermen and those who by accident or intent fall into the canals. In one instance a waterborne epidemic occurred in which the water was presumably contaminated by rats from a neighboring sewer. The manner in which the spirochetes enter the body is not known. but very possibly it is though minute cuts and abrasions in the skin or via the alimentary tract.

CANINE LEPTOSPIROSIS

The role of dogs in the transmission of infectious jaundice has been of considerable interest. Dogs suffer from two forms of leptospirosis, the one an acute jaundice ("yellows") similar to acute Weil's disease in man and the other a nonjaundice type known as Stuttgart disease or canine typhus. Lept. icterohemorrhagiae may infect dogs and probably is responsible for the former type of disease, while a canine leptospira, Lept. canicola, produces the latter form. The relative incidence of the two infections in dogs is not known with certainity: some have suggested that as many as 50 per cent of cases of canine leptospiroses are icterohemorrhagiae infections. Lept. canicola infection in dogs appears to be relatively common in the United States, and natural infection with other serotypes occurs also. Surveys² have shown that 13 to 32 per cent of dogs are seropositive, and 11 per cent of the positives are carriers of the infection. In addition to Lept. canicola and Lept. icterohemorrhagiae, which are found most often, dogs in this country are also infected with Lept. grippotyphosa, Lept. pomona, Lept, autumnalis, and Lept, ballum.

SWAMP FEVER

Na A Turk Land William Vol. Vinc. Fred and

A leptospiral infection prevalent during the summer and early autumn months in Bavaria, ⁸⁴ Silesia, and the Volga region⁸³ is variously known as swamp fever, Schlammfieber, autumn fever, water fever, field fever, harvest fever, mud fever, and slime fever. It has also been reported from Holland, It is found among field workers following floods or in swampy districts particularly during the hav harvest. Clinically it closely resembles Weil's disease in a mild formthe case fatality is less than 1 per cent - but there is no jaundice except occasionally in the sclera. The causative microorganism. Lept. grippotyphosa (Spirochaeta grippotyphosa), is immunologically distinct from Lept icterohemorrhagiae. The reservoir of infection is the field mouse, Microtus arvalis. The wood mouse, Apodemus sylvaticus, and the bank vole, Evotomys glareolus, are less often infected. A very similar disease is found in the rice fields in Italy, but the etiology appears to be diverse in that a number of species of leptospira have been found. in many instances apparently identical with those found in the Far East.

Reservoirs of infection with many serotypes of leptospira also occur in wild animals, including skunks, raccoons, mongooses, muskrats, opossums, and nutria,³⁶ as shown by both serological evidence and isolation and identification of the leptospira. Human infection may be acquired from these sources, such as Fort Bragg fever, an infection with *Lept. autumnalis*, apparently acquired from raccoons.⁷⁵

Domestic animals, especially swine and cattle, in addition to dogs as described above, also serve as sources of human infection. Swineherd's disease (Bouchet-Gsell disease), found in Switzerland and elsewhere,64,65 is often an infection with Lept. pomona. A number of serotypes have been found in infections of cattle, and in some cases it may be disseminated among the animals through the agency of infected water.43 Human infection from this source tends to be an occupational disease.⁷⁸ In the United States leptospirosis is more widespread than had been supposed, in cattle as well as in the larger wild animals; for example, infected cattle have been found in all counties in Iowa, 109 and a variety of serotypes occur in human infections derived from this and other sources.54

LEPTOSPIRAL INFECTIONS OF THE FAR EAST

A number of leptospiral infections occur in the Far East. They are similar to swamp fever in that they are febrile, jaundice is rare except in the sclera, and the case fatality rate is low. Japanese seven-day fever, or nanukayami, is prevalent in Japan in the autumn. The causative agents is Lept. hebdomadis and is carried by the field mouse, Microtus montebelli. A common sequel to the infection is opacification of the vitreous humor. Hasami fever is a similar disease also prevalent in Japan and caused by Lept. autumnalis (Lept. akiyami A). The reservoir of infection is the mouse Apodemus speciosus, and possibly other species of field mice and rats are infected.

Leptospirosis of heterogeneous etiology is not uncommon in Indonesia. The disease which occurs in Sumatra, known as Rachmat infection, is caused by Lept. autumnalis and is presumably identical with Hasami fever in Japan. Other infections are known by various names, including Andaman A fever, Salinem infection, and the like. The causative organism of Andaman fever appears to be Lept grippotyphosa. The name Lept. pyrogenes has been given the causal agent of Salinem fever. The remainder of the leptospiroses appear to be largely infections with Lept. bataviae, which is found in natural infections in rats, including Rattus norvegicus and R. decumanus (in Japan), and in field mice including Apodemus sylvaticus, Micromys minutus, and M. soricinus.

Mild fevers of leptospiral etiology are endemic in Queensland in Australia, and a number of immunologically distinct varieties of leptospira have been isolated. That designated Lept. pomona is the causative agent of the affection known as Pomona fever, and other species named Lept. australis A and Lept australis B are responsible for febrile disease designated Mossman fever, coastal fever, and the like. Additional varieties have also been reported, but it is not as yet clear that they are distinct species.

Geographical separation of the leptospiroses is not sound, for some of these microorganisms occur in widely separated regions. Thus Lept. grippotyphosa is found in Indonesia and Lept. bataviae and Lept. pomona have been reported as the etiological agents of swamp fever in Italy. Lept. icterohemorrhagiae and Lept. canicola occur in human beings and in dogs, and Lept. pomona has been found in naturally occurring infections of cattle in this country.

SAPROPHYTIC LEPTOSPIRA

Leptospira closely resembling Lept. icterohemorrhagiae have been isolated from water by a number of workers. These nonpathogenic forms have been termed Lept. biflexa in this country and in England, and Spirochaeta pseudoicterogenes by the German workers. Their relation to the pathogenic leptospira is uncertain.

Rat-Bite Fever (Spirillum morsus muris)

There are two distinct kinds of disease which may follow the bite of rats and they are designated rat-bite fever. One, Streptobacillus moniliformis infection, is discussed elsewhere (Chap. Twenty-seven). other, known in Japan as sodoku, is caused by a spiral microorganism discovered by Futaki and his co-workers in 1916. Following the bite of an infected rat, the original wound heals, but, after an incubation period of 10 to 22 days, becomes inflamed and painful. Fever, swelling of the lymph glands, skin eruptions, and other symptoms occur. The fever is of the relapsing type, with paroxysms at fairly regular intervals, usually about once a week, which continue to recur for one to three months or longer. The case fatality varies from 2 to 10 per cent.

The characteristic spiral microorganism

has been found in the swollen local lesions of the skin and the enlarged lymph glands and also in two instances in the circulating blood. Guinea pigs and mice may be infected by the inoculation of blood or fluid expressed from the local lesions. The microorganism is found in about 3 per cent of the house rats in Japan. The rat is not the only vector of the infection, for cases of what is apparently the same disease have been traced to the bite of the cat, dog, pig, ferret, squirrel, and weasel.

The disease has long been known in Japan and has been reported from many localities all over the world. Brown and Nunemaker¹⁷ have found a total of 125 cases reported in the United States from 1916 to the end of 1940. What proportion of the earlier reported cases were Streptobacillus infections

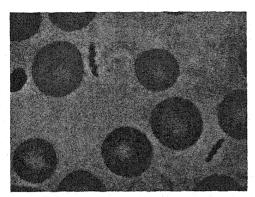

Figure 228. Spirillum morsus muris in blood of an inoculated mouse. (Van Sandt.)

is, of course, problematical. Of 40 cases reported from 1931 to 1940, the spirillum was demonstrated by animal inoculation in 17; of these, 11 resulted from rat bite and the remainder had a history of mouse bite, cat bite or scratch, contact with dogs, or trauma without known animal contact. The natural occurrence of spirochetes in laboratory mice, rats, and guinea pigs is a source of error to be guarded against in laboratory diagnosis by animal inoculation. There is little doubt that the affection is much more common than appears from the records, for the cases occur sporadically and their true nature has often gone unrecognized.67 The infection has been produced in man by artificial inoculation for the treatment of paresis; according to Brown and Nunemaker there are 104 such cases in the English literature.

Not a great deal is known of the immune response to the infection other than that a spirillicidal antibody is produced that is also responsible for immobilization of the spirilla in immune serum. Savoor and Lewthwaite⁹⁵ have observed that a positive Weil-Felix reaction of the OXK type is produced in experimental animals, but the antigen shared with these strains of Proteus is distinct from that which is responsible for the spirillicidal antibody.

The spiral microorganism of rat-bite fever has been variously classified as Spirochaeta morsus muris, Borrelia muris, Spirillum minus, etc. It is shorter (2 to 5 μ in length) than the recognized spirochetes, is relatively rigid, and possesses polar tufts of flagella which give it a rapid darting motion unlike the flexible undulating movements of the spirochetes. The clinical symptoms of the disease are typical of spirochetosis.

Arsenicals have been used chemotherapeutically in the past, and the bacteria are sensitive to penicillin and the broad-spectrum antibiotics; penicillin-tetracycline therapy was found highly effective in one instance. Originally given the name Spirochaeta, this microorganism was found to be identical with *Spirillum minus* found by Carter in the blood of a rat in India. It is, perhaps, best given the independent generic name Spirillum and considered with the spirochetes.

Chapter Thirty-four

MEDICAL PARASITOLOGY

By ROBERT M. LEWERT, Sc.D.

The division of microbiology termed medical parasitology encompasses the animal agents of human disease. It may seem incongruous to include in "microbiology" organisms such as the larger helminths whose dimensions are measured in meters or liters, as is the case with the cestodes Diphyllobothrium and Echinococcus. There is, however, an entire spectrum of dimensions of parasitic animals, including the intracellular protozoans, only a few microns in diameter. Within the large group of phylogenetically dissimilar animals parasitizing man, parallel evolution has resulted in numerous instances of superficial similarity of form and host-parasite relationship. Physiological interactions with and dependencies on the host occur which we more commonly attribute to bacteria, viruses, and rickettsiae.6, 160

These similarities include such obvious disease production as anemias, dysenteries, encephalitis, and pneumonitis, as well as more obscure effects, such as hypersensitive and allergic responses. However, in contrast to other parasites, phylogenetically related parasitic animals are typified by variety and contrast rather than unifying principle in their disease production, physiology, morphology, life cycles, and other characteristics.

Knowledge of the large parasitic roundworms such as Ascaris and Dracunculus and the large tapeworms and flukes is evident in the earliest writings, and the elucidation of a number of complex parasite life histories and appropriate control measures preceded much of our detailed knowledge of other microbial disease.^{68, 137}

Descriptive parasitology has been a productive division of zoological science, re-

sulting in a tremendous body of knowledge on the complex life cycles and morphology of these forms. This supplied the knowledge of the minute morphologic detail needed for parasite identification for, in contrast to the bacteria, diagnostic, metabolic, culture characteristics were largely unobtainable by usual procedures.21, 98, 140 Investigations of parasite physiology have been difficult because of inability to cultivate most forms free of their hosts. Some demand several hosts, each physiologically necessary to the cyclic development of the parasite, and difficulties of culture might be anticipated. Others of such apparent morphological and cyclic simplicity as the intestinal amebae have also resisted intensive research directed at their cultivation on defined mediums in the absence of other living cells.

For these reasons, techniques of immunization, effective chemotherapy, and practical control measures have lagged behind those developed to combat other disease agents. Consequently, the current world incidence of infection and disease produced by parasitic animals remains high and in some areas is increasing. Even in the case of malaria, which is being attacked on a global scale, annually 1.2 billion individuals live in areas where they are exposed to infection, 200 million cases are reported, and at a conservative estimate 1.5 million deaths result.124, 127 Among the helminths the most important example is the schistosome complex which currently parasitizes approximately 4.5 per cent of the world's population and is increasing its distribution and prevalence in much of its range. 101, 122 The roundworms parasitizing man are so successful that the number of infections

exceeds the world population. Although many of these singly are relatively benign or only slightly debilitating to an otherwise healthy host, multispecies infections are the rule in many areas of the world where their effects are further enhanced by subsistence nutritional levels of the host.

Parasitic animals are of such importance to tropical medicine that this has resulted in the popular misconception that parasitic disease of man is exclusively a problem of the tropics.95, 139 Natural transmission of Ascaris and Trichinella extends into arctic areas, and the classic endemic areas of hydatid (Echinococcus) disease are sheep raising areas, including Iceland.24, 43, 44, 76 Until the relatively recent past the midwestern United States and much of Europe were malarious areas. 62, 127 Although more common in tropical areas, autochthonous amebic dysentery persists in causing individual and occasionally epidemic problems in northern urban communities, 100, 111 while Enterobius and Hymenolepis are dependent on the urbanization of man rather than on climate for survival. In addition, because of increased travel and protracted incubation periods of many parasitic diseases, numerous isolated instances of infection with exotic species are diagnosed in all major northern urban areas.

Disease-producing parasites of man are found among the unicellular animals (protozoa), the worms (platyhelminthes, nemathelminthes, and acanthocephala) and the arthropods. The latter include many species of insects and arachnids of importance as parasites, disease vectors, intermediate hosts, and forms damaging by virtue of their toxic chemical, traumatic, or sensitizing properties. Only those of importance as intermediate hosts of parasites will be included in this chapter. It is not possible here to present material on the arthropods as disease agents and reference is made to various texts on the subject for full coverage. 65, 71 Over 150 protozoan and helminth parasites have been reported from man with approximately one-third of these being common associates. Representatives have been selected for inclusion in this chapter to serve as illustrative examples or for their intrinsic importance in disease production. References for further study and more detailed coverage include standard clinical texts and selected texts and papers cited. 24, 43, 44, 76

The Protozoa

The protozoa are usually thought of as single-celled animals, analogous to the individual cells composing the higher animals. Some authorities, however, prefer to regard them as acellular organisms, not functionally subdivided into cells. Both views have value, for the protozoa evince properties both of single cells and of complete organisms.

Many thousand species of protozoa have been described, though less than 35 well-defined species are known to parasitize man. They constitute an exceedingly heterogeneous group of organisms, varying in size from that of the larger bacteria to several millimeters in diameter, in complexity of structure from a simple, formless cell like Entamoeba histolytica to organisms of far greater intricacy than many metazoa, and in life cycle from the binary fission of Trichomonas vaginalis to the alternation of hosts and of asexual and sexual reproduction exhibited by the malarial parasites. §77, 90, 97

The systematics of the protozoa is complex⁹¹ and no single scheme of classification is uniformly acceptable. Division of the phylum Protozoa into four subphyla plus a small group with uncertain affinities provides a satisfactory simplified method of encompassing the species parasitizing man.

Subphylum Sarcodina (amebae), characterized by the ability to produce from the cell transient finger-like protoplasmic processes (pseudopodia) for the engulfment of food and for locomotion. Many free-living species as well as parasitic forms exist. The parasites characteristically are simple in appearance without morphologically complex organelles and multiply without any known sexual stages. All have a motile trophozoite stage during which multiplication is by binary fission. Many species also form a cyst in which stage two or more nuclear divisions may take place preceding the multiplication effected when the cyst infects the host. Amebae of man are primarily found in the digestive tract.

Subphylum Ciliophora (ciliates), having numerous, short, bristle-like, cytoplasmic locomotor organelles termed cilia. Most have two types of nuclei (macronucleus and micronucleus) with multiplication by binary fission and with conjugation in some forms.

There are many free-living, commensal and symbiotic species with but a single form, *Balantidium coli*, occurring as a bona fide parasite of man.

Subphylum Mastigophora (the flagellates), characteristically having throughout or at some point in their life cycle relatively long, fllamentous protoplasmic processes used in locomotion. These flagella may be multiple or single. Those intracellular parasitic stages lacking flagella may be recognized by a parabasal body, a rod-like structure associated with the flagellar origin. Division is by binary fission. Evidence for a sexual cycle in the hemoflagellates has been presented but is not wholly acceptable. Numerous free-living, parasitic, and commensal species exist. Flagellates parasitizing man are found in the intestinal and genital tracts, free in the circulation, and as intracellular parasites primarily of the lymphoid-macrophage system.

Subphylum Sporozoa, an artificial polyphyletic grouping of parasites characterized by the lack of well-defined organelles of locomotion and with an alternation of sexual and asexual reproduction. All members of this group are parasitic and many produce structures of varied morphology which have been designated as spores and which contain one to many infective individuals termed sporozoites. The malaria parasites (Plasmodia) and the intestinal coccidia of man belong

to this group.

A separate group superficially similar to the sporozoans, of uncertain affinities, has been characterized as a class, Toxoplasmasida, having no spores and with asexual reproduction. This group would include Toxoplasma and Sarcocystis of man as well as a variety of parasites of other vertebrates.^{90, 91}

To supplement this skeleton classification and the material to follow, a number of basic texts and taxonomic studies are available.^{87, 97}

THE INTESTINAL AMEBAE (Sarcodina)

Entamoeba histolytica. Lewis in 1870 and Cunningham in 1871 first reported amebae, probably the nonpathogenic Entamoeba coli, in human feces. Lösch in 1875 described what were apparently E. histolytica in the stools and intestinal ulcers in a fatal case of dysentery. He found similar ulcers containing the amebae in an artificially infected dog.

Characteristics and life cycle. The active ameba as seen in the intestinal ulcers of dysentery cases is a granular colorless or pale greenish mass of cytoplasm, 15 to 50 (usually 20 to 30) μ in diameter. It has no definite shape. Locomotion is accomplished by the sudden extrusion of clear projections of cytoplasm, the pseudopodia, the remainder of the cell body following these pseudopodia in a flowing motion. The granular cytoplasm often contains red blood

cells or debris of tissue cells in various stages of digestion. These are the food engulfed by the ameba. The nucleus may be visible as a delicate ring of granules. Reproduction in this stage is by binary fission, the nucleus undergoing a type of mitosis and the cytoplasm then dividing to produce two daughter amebae like the original. In organisms fixed and stained with hematoxylin the nuclear structure is characteristic, consisting of a thin peripheral layer of fine black granules and a central small black dot, the *karyosome* (Fig. 229). The entire nucleus is generally 4 to 5 μ in diameter.

Infected persons with diarrhea or dysentery pass active ameboid parasites in their stools. In the intestinal lumen of a carrier, however, the ameba loses its ingested food particles, shrinks to a diameter of 10 to 20 μ (rarely less), rounds up and becomes essentially nonmotile, sending out only an occasional pseudopodium. This is the precystic stage, which soon secretes about itself a clear wall, becoming the partially resistant cyst. In its passage down the intestine the cyst continues to develop, acquiring a vacuole of glycogen and one or more ovoid rods of black-staining material, the chromatoid bodies. The nucleus divides into two and then four, all resembling the nucleus of the active ameboid stage though considerably smaller. In the mature cyst the glycogen vacuole soon disappears, and the chromatoid bodies persist at most for a few days.

The cyst is the infective stage, since most or all of the active ameboid stages are destroyed by gastric juice. As studied in culture, excystment consists of the emergence of a four-nucleate organism which by a complicated division process produces eight small amebae. These are the stages which initiate a new infection.

Boeck and Drbohlav in 1925 cultivated E. histolytica in Locke's solution and inactivated serum tubed over egg slants. Various modifications have been introduced, the most important being the addition of powdered rice starch, which the amebae ingest avidly. Cleveland and Collier used liver infusion agar slants overlaid with serum-saline. Balamuth devised a valuable monophasic medium consisting of buffered aqueous egg yolk infusion, with or without liver extract.

These mediums do not permit pure culture, for the amebae are dependent on living

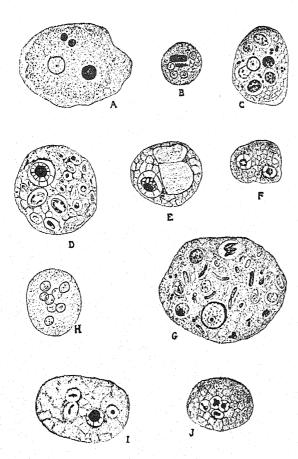

Figure 229. The amebae living in man. A. active ameboid form of Entamoeba histolytica containing three red blood cells. B, mature quadrinucleate cyst of same containing two chromatoids. E. hartmanni is similar but has smaller nuclei. C, active ameboid form of Entamoeba gingivalis. D, active ameboid form of Iodamoeba williamsi containing many intestinal bacteria. E, cyst of same showing large double vacuole which in life was filled with glycogen. F, ameboid form of Dientamoeba fragilis containing two nuclei, G, large active ameboid form of Entamoeba coli containing intestinal bacteria and debris, H, mature octonucleate cyst of same. I, ameboid form of Endolimax nana. J, mature quadrinucleate cyst of same. $A, B, C, G, and H, about \times 1300 (Dobell), D, E, F,$ and $J_1 \times 3000$ (Taliaferro and Becker). $I_1 \times 3000$. (Taliaferro in Hegner and Taliaferro's Human Protozoology, courtesy of The Macmillan Company.)

bacteria for growth. The protozoan Trypanosoma cruzi has also been utilized as an associate for culture of the amebae. Shaffer and Frye obtained amebic growth in the presence of antibiotic-inhibited bacteria. Cultivation of one strain of E. histolytica in a cell-free system is now possible and is being utilized for antigen preparation and immunological studies. This is the first extensive truly axenic cultivation of this species, although not vet applicable to all strains.35 The related tissue-invading, pathogenic parasite of snakes, E. invadens, has been cultivated successfully in a cell-free liver extract medium. E. histolytica is a strict anaerobe and requires a pH between 6.5 and 7.0 approximately.99

Amebiasis and amebic dysentery. The amebae normally inhabit the large intestine. While some workers believe that they proliferate only in the tissues, the evidence indicates that they may also multiply in the intestinal lumen, living, as in culture, on a diet of microorganisms. ⁸⁶

In the wall of the colon the parasites are found in necrotic, usually noninflammatory

lesions varying from minute erosive patches to more or less extensive, undermined ulcers of the submucosa. The abundance and severity of the lesions determine the clinical picture. The great majority of infected individuals are carriers exhibiting no symptoms. Clinical cases range from moderate diarrhea to acute dysentery with passage of blood and mucus, extreme weakness, and, not infrequently, death. A varying proportion of individuals with amebic dysentery show necrotic abscesses of the liver, or may show a generalized hepatitis of amebic etiology. Initially the liver abscesses are bacteria-free but may become contaminated secondarily.89,94 These also occur occasionally in individuals who give no history of intestinal symptoms of infection. Lung abscesses, usually produced by extension from the liver through the diaphragm, occur in a small number of individuals, and abscesses have been reported in practically every organ of the body.

The entire question of host-parasite relationships in amebiasis including disease production is complex and controversial.42,66,102 The lack of agreement even in the morphological bases for diagnosis of the species causing amebic disease has also complicated the picture.15, 20, 121 Strains of the species vary in their morphology and in their pathogenicity for man. 67, 108, 109 Some rapidly lose pathogenicity in culture, and human pathogens may or may not be pathogenic for laboratory animals.64 Strains of human origin, pathogenic for animals, have been shown to be completely innocuous in human voluteers.9 Some investigators have presented evidence that the pathogenicity of amebae is directly related to the pathogenicity of the bacterial associates, while others refute this. The dependence of most strains of amebae in culture on bacterial associates and the inability of amebae to produce extensive lesions in bacteria-free guinea pigs lend weight to the concept of the need for synergistic bacterial associates in amebiasis.93, 115 However, as mentioned earlier, sterile amebic abscesses are found. The suggestions that individual variation in resistance and that nutritional factors are of primary importance in the severity of the disease have supporters but are also disputed.37, 49 Attempts have also been made to associate invasiveness of strains to the presence or lack of protease or mucopolysaccharidase activity with equivocal results.80, 109

IMMUNITY. There is no direct evidence. of acquired immunity to infection with E. histolytica. Natives of hyperendemic regions show acute dysentery less frequently than aliens, possibly as a result of acquired immunity. Serum antibody response to the infection is evidenced by the complementfixation test, which is positive in over 80 per cent of infected individuals. Sera from infected individuals will inhibit to varying degrees the ability of amebae in culture to ingest erythrocytes or can be shown to immobilize their locomotor activities. 138 Antibodies from infected individuals when labeled by fluorescein have considerable specificity for the infecting species and a degree of strain specificity.58,59 Immune precipitates in a gel diffusion system on a micro scale also show species specificity. A diagnostic test using an indirect hemagglutination technique has also been devised and is being utilized in some laboratories. 86, 105 As with similar systems for parasitic infections it is not possible at present to correlate these diagnostic serologic phenomena with functional immunity.

DIAGNOSIS. Diagnosis of infection with E. histolytica depends upon the finding of characteristic organisms in the stools and their morphological differentiation from the nonpathogenic amebae occurring in human feces. Cultivation has been utilized, but in cultures E. histolytica resembles the nonpathogenic E. coli so closely that differential diagnosis is often very difficult. Direct smears of fresh loose stools in warm saline may reveal the active ameboid stages. They may also be found in material taken directly from lesions in the lower bowel with the aid of the proctoscope. The M.I.F. stain of Sapero, Lawless, and Strome is valuable for temporary preparations, although permanent smears stained with iron hematoxylin give the best differentiation. In well-formed stools cysts may be expected, and these are most easily identified in iodine solutions, such as D'Antoni's iodine. The formalin-ether concentration method of Ritchie (for cysts) and the M.I.F. concentration method of Blagg et al. (for both cysts and trophozoites) are excellent for diagnosis of the light infections which may be missed by direct examination. The P.V.A. preservation technique of Brooke et al. permits shipment of material to a central laboratory for examination. 15 E. histolytica appears irregularly in the stools and, whatever the technique, repeated examinations are often necessary to establish a diagnosis. It should be re-emphasized that recovery of the organisms is only the first step in diagnosis of E. histolytica infection. The final step is the identification of the parasites. a task requiring abundant experience. Some concept of the variation between individuals can be gained by examining photomicrographs.^{21, 140} However, considerable experience is needed to exclude the commensals and smaller related forms such as E. hartmanni. The varied symptomatology and severe nature and importance of amebic disease necessitates the development of a more objective diagnostic method than presently exists. Axenic cultivation procedures and immuno-cytochemical methods being studied may produce this in the future.

CHEMOTHERAPY. Emetine has a favorable effect on the symptoms but rarely eliminates the infection from the intestine. Several iodine-containing drugs, notably chiniofon and Diodoquin, and arsenicals, especially carbarsone and Milibis, are effective in eradicating the amebae.

Several antibiotics are useful in treat-

ment. Chlortetracycline is moderately efficient, and oxytetracycline cures about 90 per cent of cases. Chloroquine and Camoquin, while useless in intestinal amebiasis, are highly curative in extraintestinal infection

Epidemiology and control. The active ameboid stages of E. histolytica die quickly after exit from the body, for they are very susceptible to drying and to changes in temperature and salt concentration. Since they are destroyed by gastric juice, they are not usually infective when swallowed. The amebic dysentery patient is therefore practically harmless as a source of infection, since only the ameboid stages occur in his stools. The cysts passed by carriers, while not at all comparable to bacterial spores in resistance, show considerably less susceptibility to conditions outside the body than do the ameboid stages. Studies utilizing cysts from culture tested for viability by cultivation show survival of several months in water at 0° C., three days at 30° C., 30 minutes at 45° C. and five minutes at 50° C. Cysts of E. histolytica are somewhat more resistant to chlorine than are enteric bacteria. It is believed that ordinary residual chlorine concentrations are unable to destroy amebic cysts, but that hyperchlorination is effective. In this connection it should be borne in mind that in the Chicago amebic dysentery outbreak of 1933 there was abundant circumstantial evidence that the infection was spread by water containing sufficient residual chlorine to kill intestinal bacteria.100

In general, the spread of E. histolytica resembles that of intestinal bacterial infections, utilizing any means by which fecal contamination reaches the human mouth. Most important are drinking water, food handlers, and houseflies. Swimming pools, though not definitely incriminated, are a potential source of infection. Viable cysts have been found in the droppings of houseflies one to two days after exposure, and flies have been held responsible for at least one important outbreak. The 1933 epidemic in Chicago referred to above was traced to local sewage contamination of drinking water in two hotels. This epidemic, in which 1409 cases were discovered and there were 98 deaths, was the first major outbreak in a city of the temperate zone. It directed medical attention to a problem which had been considered important only in the

tropics. As recently as 1955 a similar outbreak occurred in South Bend, Indiana, with contaminated drinking water as the source, re-emphasizing the fallacy in considering amebiasis an exotic infection.¹¹¹

The distribution of E. histolytica is worldwide, but temperate regions have usually a low incidence of infection. Surveys indicate a general infection rate in the United States of 4 to 10 per cent, though in some southern localities the incidence has approached 40 per cent. These figures include E. hartmanni (see below) and are probably about twice the incidence of E. histolytica alone. In the tropics the carrier rate is generally very high, often exceeding 50 per cent. Human carriers are the only important source of infection, although E. histolytica occurs naturally in lower animals, particularly rats, dogs, and monkeys. The most widely used experimental animals are dogs, cats, monkeys, rats, guinea pigs, rabbits, and hamsters.67

Control of the spread of *E. histolytica* is not basically different from that of other human enteric infections. The high incidence of carriers not known to have had clinical dysentery complicates the problem, but it is ultimately a matter of prevention of access of human feces to the mouths of susceptibles.

Other species of amebae parasitic in man. Six other species of amebae live in the human intestine. With the exception of *Dientamoeba fragilis* these are nonpathogenic and are of medical interest only because they must be differentiated from *E. histolytica*.

E. hartmanni, long considered a small race of E. histolytica, has recently been shown to be a distinct species. It differs from E. histolytica in size, the cysts being always less than 10 μ in diameter, and in size of the nuclei, which are slightly more than half the diameter of those in E. histolytica. Usually it is not distinguished from E. histolytica in diagnostic work, but in a few surveys it has been found to make up about half the infections of the histolytica type. It is nonpathogenic and can be cultured only with difficulty.

Entamoeba coli, a common species, differs from E. histolytica in several characters. The stained nucleus shows thicker peripheral chromatin blocks and a larger and usually noncentral karyosome. The ameboid stage is sluggishly and usually nonprogres-

CILIOPHORA 775

sively motile with blunt, slowly extruded pseudopodia. It ingests bacteria and other particles but rarely red blood cells. The spherical cysts average somewhat larger, 10 to 33 μ in diameter, contain eight nuclei in diameter, contain eight nuclei in the mature stage and may show chromatoid bodies with pointed or "splintered" ends.

E. polecki, a parasite of hogs and monkeys similar to E. coli but producing uninucleate cysts, has been found very rarely in man.

Endolimax nana is smaller, 6 to 15 μ in diameter in the ameboid stage. The stained nucleus shows no peripheral chromatin but a very large, nearly central karyosome. Movement is sluggishly progressive, and bacteria are ingested. The spherical or ovoid cyst is 5 to 14 μ in diameter, containing one to four minute nuclei and sometimes small spherical or rod-like chromatoid bodies.

Iodamoeba biitschlii measures 8 to 20 μ in diameter in the ameboid stage. The stained nucleus shows a large central karyosome surrounded by a layer of granules. Movement and inclusions are like those of $E.\ coli.$ The cyst is irregular in shape, 5 to 20 μ in diameter, and contains one or rarely two nuclei. Minute granules may be seen, but the most striking feature of the cyst is a large glycogen mass, staining dark brown with iodine.

Dientamoeba fragilis, seldom reported in the general population though sometimes common in institutions, is a very small form, 5 to 12 μ in diameter. It usually shows two nuclei, each containing a large multiple karyosome. It moves actively, ingesting bacteria. It has been associated with acute dysentery, and it has been suggested that it may produce low grade constant irritation with fibrotic changes producing an appendicitis.144 It is considered by some protozoologists to be an aberrant flagellate rather than a true ameba. No cyst stage is known and the binucleate trophozoite, as its name suggests, is readily destroyed. One investigation suggests that D. fragilis is transmitted via the egg of the pinworm of man, Enterobius vermicularis.²² Precedent for this is found in the cycle of Histomonas meleagridis, an ameba-like, pathogenic flagellate of the turkey which is transmitted through an Ascarid

E. gingivalis, probably the first parasitic ameba seen, was reported by Gros in 1849 from the tartar between the teeth. It has no

known cyst stage and is apparently transmitted in the ameboid stage by contact. Formerly suspected of an etiological role in pyorrhea, it is now considered harmless.

CILIOPHORA

Balantidium coli is the largest protozoan parasite found in the intestine of man, reaching a size of $150 \times 120 \mu$. The organism may cause an acute bloody dysentery similar to amebiasis, commonly penetrating into the muscularis mucosa and occasionally perforating the intestine.4 Carrier infections without symptoms occur in man, and the world incidence is estimated at less than 0.7 per cent. Swine are almost universally infected and human infection usually derives from food or water contaminated with the resistant cysts from this source. Moderate to severe pathology is produced in other primates, and infections naturally occur in the rhesus monkey, chimpanzee, dog, and Norway rat. Balantidium may be cultivated on a variety of mediums. Carbarsone is an effective chemotherapeutic agent, although Diodoquin and the tetracyclines have also been used successfully in treatment.

INTESTINAL FLAGELLATES (Mastigophora)

The mastigophora of the digestive tract and genital organs, illustrated in the accompanying figure, are typically lumen parasites. The common cosmopolitan species of enteric flagellates, Chilomastix mesnili, Trichomonas hominis, and Giardia lamblia, are host-specific although a number of less common and less specific coprophagic forms are found in man. None are generally considered as important pathogens. However, Giardia is commonly associated with erosion of the epithelium of the duodenum and also with an irritation of the gallbladder. Intense infections in children are considered by some to cause dysentery, celiac syndrome, or a sprue-like condition.32 The parasites and the associated intestinal symptoms disappear following treatment with atabrine.

Trichomonas vaginalis is a cosmopolitan common parasite of the vagina and male genital tract. Infection is commonly symptomless but may produce in the female a

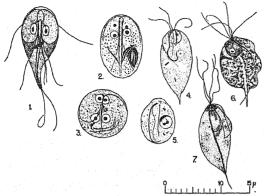

Figure 230. Flagellates of the human intestine and genital tracts, hematoxylin stain. (Mackie, Hunter, and Worth: A Manual of Tropical Medicine. 2nd ed.)

severe vaginitis and in the male may occasionally be associated with an urethritis. Transmission occurs primarily through sexual intercourse, as the parasite has no resistant stage. Variation in virulence is related to strain of the parasite. It is interesting that infected individuals also are usually infected with the nonpathogenic buccal flagellate, *Trichomonas tenax*. 19

Flagellates related to the above such as *Trichomonas foetus* may be highly pathogenic. The latter, also transmitted by coitus, causes contagious abortion in cattle. *Trichomonas gallinae*, a common parasite of the domestic pigeon, has virulent pathogenic strains producing lesions in the upper digestive tract and associated structures. Virulence transformation of avirulent strain forms treated with homogenates of pathogenic strains has been reported for this species.⁷⁰

Chilomastix and Giardia are spread by ingestion of material contaminated with human feces containing their cysts. Trichomonas has no resistant cyst but the trophozoite may remain viable for more than an hour on dry fomites.

HEMOFLAGELLATES (Mastigophora)

The flagellate protozoa occurring in the blood stream or as intracellular parasites of

man are termed hemoflagellates. All are members of the family Trypanosomidae with seven species found in man, viz., Trypanosoma rhodesiense, T. gambiense, T. cruzi, T. rangeli, Leishmania donovani, L. tropica, and L. braziliense. All have probably evolved from parasites of the intestinal tract of insects and those parasitizing man still require blood-sucking insect vectors or intermediate hosts for normal transmission.⁵¹ During their life cycles hemoflagellates display a variety of morphological types in regular stages. Since these types have been associated with particular genera the stages are named for the genera they resemble. As indicated in the accompanying figure these are the trypanosomal, crithidial, leptomonad, and leishmanial forms. The trypanosomal form is characterized by having a flagellum arising from the posterior of the cell, attached to the cell by an undulating membrane running the length of the body, and ending anteriorly as a free flagellum. In the crithidial form the flagellum arises just anterior to the nucleus with the undulating membrane being correspondingly reduced. The flagellum in the leptomonad stage originates near the anterior end of the body with no associated membrane, while in the ovoid leishmanial stage no free flagellum is present. The structures associated with the point of origin of the flagellum, the kinetoplast and basal granule, may still be seen in the leishmania and are of diagnostic importance.

The medically important hemoflagellates fall into three groups in two genera. Trypanosoma gambiense and related forms exhibit the trypaniform stage in the vertebrate host and trypaniform and crithidial stages in the invertebrate. T. cruzi exhibits all four stages in the vertebrate host, trypaniform and crithidial stages in the invertebrate. Members of the genus Leishmania exhibit only the leishmaniform stage in the vertebrate and the leptomonad stage in the invertebrate host.

Reproduction of all forms is by binary fission. The nucleus, blepharoplast, and parabasal body divide, a new flagellum arises from one blepharoplast, and the cytoplasm divides longitudinally to produce two daughter cells. In the species with which we are concerned, the leishmaniform stages are intracellular in the vertebrate host. The flagellated stages inhabit body fluids of vertebrates or the alimentary tract of insects.

THE TRYPANOSOMES

Trypanosoma gambiense. Ford observed, in the blood of a Gambian native, a flagellate which was described by Dutton in 1902 as T. gambiense. In 1903, Castellani observed similar flagellates in the cerebrospinal fluid of a sleeping sickness patient in Uganda. Bruce and Nabarro, in 1903, transmitted T. gambiense to monkeys with a tsetse fly, and Kleine, in 1909, showed that the parasites underwent a cyclic development in the fly.

Characteristics and life cycle. In the blood and lymph of early cases of African sleeping sickness T. gambiense exhibits the trypaniform stage, which in fresh preparations may be seen wriggling among the erythrocytes. It measures 15 to 40 μ in length, varying from short broad forms with no free flagellum beyond the undulating membrane to long thin forms with a free flagellum. Reproduction, as in all members of the family, is by binary fission. The transmitting insect, a tsetse fly (Glossina), becomes infected by ingestion of the parasites in infected blood. In the stomach of the fly those flagellates which survive multiply as trypaniform and crithidial stages, first in the crop, stomach, and intestine and later in the salivary glands.

Here they form infective parasites, which are injected by the bite of the fly 20 days or more after its infecting blood meal.

On NNN medium, a concentrated blood agar, the parasites multiply to a limited extent. Continuous cultivation has been

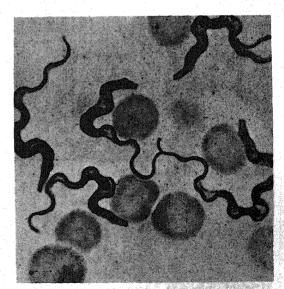

Figure 232. Trypanosoma gambiense in stained blood film. About × 2000.

achieved in some instances, but it is too difficult to be of practical value. Abundant multiplication occurs on the chorioallantoic membrane of the developing chick embryo. Development of a related species, *T. vivax*, to the infective stage in tsetse fly tissue culture has been accomplished.¹⁵¹

African sleeping sickness. The incubation period following an infective tsetse fly bite varies from two or three weeks to several months. The first stage of the human disease is a systemic infection in which the parasites are found chiefly in the blood but also in the lymph. Irregular fever is generally the first symptom. Somewhat later, as the parasites come to predominate in the lymph nodes, these organs and the spleen are enlarged, and anemia and wasting are seen. Cardiac injury may be prominent, and edema is often present. This stage gradually gives way to the sleeping sickness stage, in which the parasites are most abundant in the cerebrospinal fluid, occurring less commonly in the lymph. The central nervous system exhibits the prominent lesions, typically resulting in somnolence, apathy, and weakness, less commonly in mania and other violent manifestations. Coma and death are the final outcome. Typically the course is of several months' duration, but in parts of East Africa the disease develops more rapidly, invasion of the central nervous system occurs early, and death frequently results from cardiac injury before the typical sleeping sickness stage is reached. In the blood of laboratory animals infected from cases in this area, about 5 per cent of the flagellates are short, showing posterior nuclei; this is true only rarely in the parasites from other areas. Because of these differences in morphology and pathogenicity and the fact that transmission involves different species of tsetse flies, Stephens and Fantham separated the East African parasites as a different species, T. rhodesiense. Most authors now consider this a local race of T. gambiense.33

IMMUNITY. Spontaneous recovery is said to occur occasionally in African sleeping sickness. Except for this there are no data available on natural or acquired immunity in man. In rats and mice T. gambiense and related parasites produce rapidly fatal parasitemia, while in guinea pigs and some other hosts they show a characteristic relapsing type of infection. After a period of unchecked multiplication, the organisms are rapidly destroyed, only to reappear in a few

days and repeat the cycle. An antibody arising in the serum of a guinea pig at the time of crisis destroys parasites of the strain present before the crisis, while the strain present after flagellates have reappeared is resistant to this antibody. This phenomenon has been observed in animals infected originally with a single parasite, indicating that the change in antigenic structure cannot depend on selection alone but must involve adaptive modification of the parasite.

DIAGNOSIS. Various serum reactions are observable in African trypanosomiasis but are not dependable for diagnosis, chiefly because of the antigenic lability of the parasites. Laboratory diagnosis depends on the finding and morphological identification of the organisms in blood, lymph node juice, or cerebrospinal fluid. Dry smears stained with blood stains, such as Wright's, are used, either of the whole fluid as obtained or of centrifuged specimens. In the case of blood, thick or thin films may be used. The parasites are usually scarce, and a negative finding in any one of the body fluids is of little significance.

Epidemiology and control. Rare instances of probable venereal infection have been reported. However, the normal transfer of infection occurs by the bite of tsetse flies as described above. Two species of flies are of most importance, Glossina palpalis in West Africa and G. morsitans in East Africa. where the more virulent Rhodesian form of the disease occurs. Other species of importance are G. tachinoides, G. swynnertoni, G. pallidipes, and G. austeni. These insects are relatives of the common housefly. They are limited to tropical Africa and a small area in South Arabia, and the human disease is confined to their range. They resemble the housefly in appearance except for the long narrow proboscis, which is held straight forward from the head, and the manner of folding the wings at rest, flat on the back with one directly above the other. Both males and females bite and can transmit the disease. They bite exclusively by day. The larvae develop completely in the body of the female, are deposited singly on loose soil or sand in well-shaded places, and quickly burrow into the soil to pupate. After four to eight weeks the adults emerge. G. palpalis breeds almost entirely near water and is thus more limited in local distribution than G. morsitans, which is less dependent on shade and moisture.

The significance of wild animals in the spread of African sleeping sickness has long been disputed. Various large wild animals, especially the sitatunga antelope, harbor the flagellates, usually without symptoms, and they have been shown to maintain the infection for long periods in the absence of human reservoirs. However, most authorities agree that man is usually the source of infection. The incidence of human infection varies widely. It is not commonly higher than 2 per cent at present, though in the past villages were observed with infection rates as high as 50 per cent, and catastrophic epidemics have occurred.

The variety of control methods in use testifies to their relative ineffectiveness. Several valuable drugs are available for treatment of the human infection, a method whose success is proportional to the local significance of man as a reservoir of infection. Tryparsamide and other arsenicals are effective in all stages of the disease, though less so in the Rhodesian form, where Bayer 205 (suramin) is more active. This drug is useless in the sleeping sickness stage of the disease but is effective during the first stage and has the particularly valuable property of protecting against infection for at least three months after administration. A new series of diamidine compounds represented by pentamidine shows genuine promise. Pentamidine cures existing cases and protects against infection for at least six months after administration. Hundreds of thousands of African natives have received this drug in mass treatment campaigns, and the resulting reduction in incidence of infection suggests that this is the most effective control measure available.

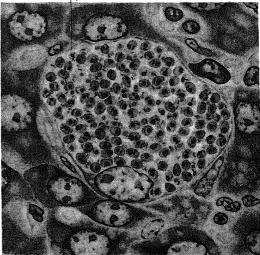

In some areas mass destruction of the reservoir game animals has been attempted, but the success of this measure is doubtful. Where the human and animal infection rates are particularly high, wholesale removal of human populations has been carried out. Control of migrants, a perpetual problem in much of Africa, is utilized in some districts in an effort to minimize spread of the disease.153

The life cycle and complex behavior of the tsetse flies make their control exceedingly difficult. Traps and hand-catching have greatly reduced the fly population in some regions. Inspection and fumigation of vehicles have been used to limit the spread of tsetse. The best single method is clearing of forest and brush, particularly along streams and around villages, which destroys the breeding and resting places of the flies.

Trypanosoma cruzi. Chagas, in 1909, discovered intermediate stage flagellates in the hindgut of the bug Triatoma megista in Brazil. He showed the infectivity of these flagellates for mammals and later found trypaniform stages in children with a characteristic disease, now known as Chagas' disease. He described the organism as Schizotrypanum cruzi, but it is now called T. cruzi by most authors.

Characteristics and life cycle. The parasites as seen in the blood of early cases of Chagas' disease are of the trypaniform type, fundamentally similar to those of T. gambiense but smaller, about 20 μ in length, and with the posterior end pointed. No multiplication occurs in the blood. The predominant phase in man and experimental animals is a small, rounded nonflagellate stage, 3 to 5 μ in diameter, occurring in clumps in various tissue cells-heart muscle, macrophages, and endothelium. These organisms have a nucleus and parabasal body as described above. They multiply by binary fission, producing dense clumps of organisms which fill the infected cells. Small numbers of trypaniform stages are apparently continually produced and shed into the circulating blood from the nests of intracellular nonflagellate parasites.

Infected Kupffer cell

Liver cell

Crypt epithelium ---

Figure 233. Leishmaniform stage of Trypanosoma cruzi Tulahuén strain in Kupffer cell of liver. (Taliaferro The second secon

Various bugs of the family Reduviidae acquire the infection from a blood meal containing the trypaniform stages. These become crithidial flagellates in the midgut and hindgut, where they multiply to produce infective trypaniform flagellates two to three weeks after the infecting blood meal. These organisms are shed in the feces of the bug. They infect man by entering the wound caused by the bite of the infected bug or by penetrating the mucosae, particularly of the mouth or eye.

Continuous culture of *T. cruzi* on NNN medium and in simpler broth mediums is relatively easy. The parasites multiply as trypaniform and, predominantly, crithidial flagellates. The nonflagellate stages have been grown in tissue cultures of macro-

phages from infected animals.

Chagas' disease. Chagas described the infection from a region having serious endemic goiter, and most of his cases had marked thyroid pathology. It has since been shown in other regions that the goitrous manifestations he described are not part of Chagas' disease. The incubation period is one to two weeks. Irregular fever and edema, particularly of the eyelids (Romaña's sign), characterize the acute phase, and there is considerable enlargement of lymph nodes, spleen, and liver toward the end of this period. The acute disease is rare except in small children, in whom occur almost the only deaths attributable to the infection. The chronic disease, which occurs in adults or following the acute stage in children, varies in symptomatology with the localization of the parasites but is most often characterized by myocarditis. 123

In addition to the myotropic strain, a reticulotropic strain (Tulahuén) occurs in Chile. Enlargement of the spleen and liver as well as engorgement of bone marrow may give a pathology resembling visceral leishmaniasis. Transplacental infection may occur but rarely, and the conditions of megacolon and megesophagus found in Argentina and Chile are attributed to parasitism by this species. 46, 136

IMMUNITY. Evidence concerning acquired immunity is lacking in the human disease, but experimental animals are immune to reinfection after recovery. Serum from such animals partially protects against experimental infection. The serum of human cases fixes complement in the presence of extracts of infected tissues or cultures of

T. cruzi, and the complement-fixation test (the Machado reaction), or any of several modifications of it, is widely used for laboratory diagnosis. A relatively nonpathogenic strain⁵⁷ of T. cruzi has been found to occur as a parasite of wild mammals in Maryland.¹⁶¹ Infection of mice with this strain confers immunity to superinfection with the more virulent strains.⁸⁴

DIAGNOSIS. Laboratory methods for diagnosis other than the complement-fixation reaction depend on the demonstration of the parasites. During the early stages of the human disease trypaniform flagellates may be found in stained blood smears. Later, indirect evidence of the presence of parasites may be obtained by blood culture or by "xenodiagnosis" (host diagnosis), in which laboratory-reared bugs become infected after feeding on a case. Fluorescent antibody methods, although not in widespread use, have also been shown to be of practical diagnostic value.

Epidemiology and control. Infection is normally acquired from infected bugs as described above, although occasionally the disease is acquired by direct contamination of mucosae, as in the congenital infection of infants. The chief vectors are Triatoma (Mestor) megista and Rhodnius prolixus, but about 40 species of the family Reduviidae have been incriminated. These insects are members of the order Hemiptera, or True Bugs, to which belong also bedbugs and many others. They are large insects with an elongated, cone-shaped head. Most species are predatory on other insects, but some live on vertebrate blood. They inhabit the nests of various animals and may occur in human houses of poor construction, where both the male and female insects commonly bite sleeping persons about the mouth or eyes. The total life cycle, involving egg, larval, nymphal and adult stages, occupies six to 10 months.

The human disease is widespread in South and Central America but of low incidence in most areas. It has been reported from every country in the Western Hemisphere, with the exception of Canada, Honduras, and the Guianas, as a sylvatic infection. *Trypanosoma cruzi* has been reported in Arizona, California, Georgia, Louisiana, Maryland, New Mexico, and Texas. 165 In addition two indigenous cases have been recorded in humans in Texas. 166 The possibility that more extensive infections occur

than are reported is suggested by the fact that patients in the eastern United States suffering from a diffuse myocarditis have been found to react positively to serological tests for *Trypanosoma cruzi*.⁴¹

Successful control of Chagas' disease has not been attained. The most promising methods involve destruction of infected domestic animals and improvement of human houses to exclude the insects and the reservoir hosts. There is no successful chemotherapy for Chagas' disease, the drugs useful in African trypanosomiasis being inactive in this infection.

Trypanosoma rangeli. Tejera, in 1920, described from a vector of T. cruzi in Venezuela a flagellate which he named T. rangeli. In 1942 this was obtained from humans by xenodiagnosis and since that time has been reported widely from Central and South America in the areas in which Rhodnius prolixus, its vector, occurs. Trypanosome division takes place in the peripheral circulation of man, dog, and monkeys with no leishmaniform stages demonstrated. No clinical manifestations are known and two experimental infections in man were without symptoms. In contrast to T. cruzi, T. rangeli is transmitted to man through the bite of the insect.

Other species of Trypanosoma. A number of important diseases of domestic animals are caused by species of Trypanosoma similar to T. gambiense. Nagana is a rapidly fatal disease of the horse family, and to a less extent of cattle and dogs, occurring in a wide area of East Africa. It is caused by T. brucei, an organism very similar to the Rhodesian form of T. gambiense. A number of other species transmitted by tsetse flies are important disease agents of animals in Africa. T. evansi causes a disease of horses, camels, and mules known as surra, which is widespread in Asia, extending to Russia, Arabia, and Madagascar.

T. lewisi of rats elicits an interesting antibody, which inhibits reproduction of the parasites without killing them. This antibody, ablastin, interferes with nuclear division, and the production of nucleoprotein by the parasite. 147

THE LEISHMANIAS

Leishmania donovani. Leishman and Donovan, in 1903, described oval parasites of the macrophages in cases of kala-azar in

India. These were recognized as mastigophora when Rogers showed they developed into motile flagellates in culture.

Characteristics and life cycle. In the human disease, kala-azar, the parasites occur as nonflagellate stages, 3 to 5 μ long, in macrophages, where they resemble the nonflagellate stages of T. cruzi as shown in the accompanying figure. They multiply by binary fission until the cytoplasm of the host cell is crowded, when they escape to infect new cells. While the parasites predominate in internal organs, they occur in the skin macrophages as well, and it is probably from this site that the intermediate hosts, sandflies of the genus Phlebotomus, become infected. The parasites transform into the leptomonas stage, 14 to 20 μ long, and multiply in the midgut and foregut of the insect, which becomes infective after a week or more. The flagellates, injected by the bite of the fly into a new host, re-establish the vertebrate phase of the cycle.

L. donovani is easily cultivated in NNN and other mediums at 22° to 35° C., multiplying in the leptomonad stage as in the insect host. In tissue cultures of spleen from infected animals the nonflagellate stages

multiply abundantly.

Visceral leishmaniasis, or Kala-azar. kala-azar, is usually a chronic disease.96 Typically it begins, after an incubation period of one to four months (sometimes much longer), with a high temperature, followed by an irregular fever. The spleen and liver enlarge greatly with hyperplasia of the parasitized macrophage system. Wasting, emaciation, and edema are common. Dysentery often occurs as a result of heavy infection in the intestinal wall. The skin is typically dusky in hue, whence the name kala-azar, meaning "black fever." The skin is infected with the parasite but usually does not show lesions until months after systemic recovery when depigmented areas appear, later often becoming slightly raised papules. Anemia and leucopenia are characteristic. Adrenal insufficiency has been reported. Death is the rule in untreated cases, usually as a result of secondary infection.

IMMUNITY. Treated or spontaneously cured kala-azar is apparently followed by a lasting, solid immunity, for second infections are exceedingly rare. However, vaccines have failed to protect against or ameliorate

the disease.

DIAGNOSIS AND TREATMENT. Crucial

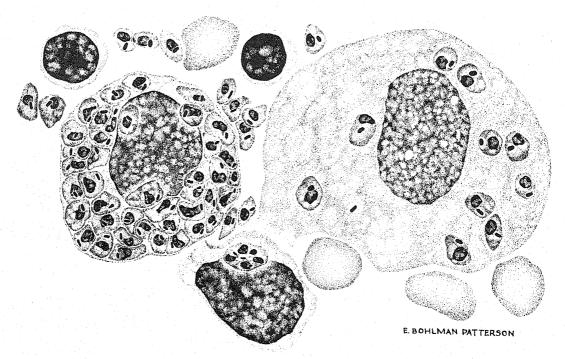

Figure 234. Leishmania donovani, free and in phagocytes, in Giemsa stained impression smear of spleen. Camera lucida; Approx. × 2000.

laboratory diagnosis of kala-azar may be obtained by the finding of parasites in biopsies of skin, spleen, liver, or bone marrow. Sternal bone marrow puncture is a reliable and safe procedure. Blood cultures may be positive. In addition, a group of nonspecific serological reactions has shown great value. These reactions depend on the fact that the serum euglobulin is greatly increased in amount in cases of kala-azar. In the formol-gel test (Napier's aldehyde reaction), positive serums form an opaque gel when formalin is added. In the antimony test a pentavalent antimonial drug causes a heavy flocculent precipitate in serums of cases. These tests are positive in over 80 per cent of cases and give false positives only occasionally with other diseases, especially schistosomiasis and malaria.

Several antimony compounds, particularly Neostibosan and Solustibosan, are effective in kala-azar. Successful treatment is often followed by dermal leishmaniasis, which may persist for several months. The drugs stilbamidine and pentamidine mentioned in connection with African sleeping sickness are also effective in kala-azar.

Epidemiology and control. Kala-azar has been reported in China, India, southern Russia, Mesopotamia, the Mediterranean littoral, southern Arabia, Equatorial Africa,

and parts of South and Central America. In Asia it is apparently a disease of man, though various lower animals, particularly dogs, hamsters, and mice, are susceptible. Infection may occur at any age but is most common in older children and young adults. In the Mediterranean area, however, it is primarily a disease of small children. Here dogs are commonly infected and apparently serve as the reservoir, since, unlike children, they show abundant parasites in the skin. The Mediterranean parasite is called by some authors L. infantum, and the South American form has been described as L. chagasi, but both are generally believed to belong to the species L. donovani.

Factors of seasonal and geographical distribution early pointed to sandflies as probable vectors, and it was soon shown that they were susceptible, developing heavy intestinal infections when fed on cases. In these flies the pharynx often becomes blocked with the simple flagellate stages, and in their vigorous efforts to feed, the "blocked" flies apparently are more likely to inject parasites.

The sandfly vectors belong to the genus Phlebotomus of the family of small flies, Psychodidae. The most important species are *Phlebotomus argentipes* in India, P.

chinensis in China, and P. major and P. perniciosus in the Mediterranean region. The vectors in other areas are as yet unknown. The adult flies are minute, night-biting insects. They fly weakly and travel very short distances but penetrate ordinary window-screening with ease. The larvae develop in loose damp soil or debris, mostly in cracks in walls, cliffs, caves, etc., the entire life cycle requiring one to two months.

The transmitting insects can be controlled by cleaning up potential breeding places or by spraying them with DDT. Treatment of human cases is also widely used for control

of the spread of kala-azar.

Leishmania tropica. L. tropica was discovered by Wright, in 1903, in an Armenian patient in Boston. Morphologically and culturally identical with L. donovani, it differs in infecting primarily the skin, where it proliferates in the macrophages of the subcutaneous tissue. In man, dogs, and wild rodents it produces large single or multiple ulcers, usually of exposed parts of the skin, known as oriental sore. These lesions appear after an incubation period of 10 days to several months. They increase to a diameter of 1 to 3 cm. and heal spontaneously after several months to leave a disfiguring scar. Permanent immunity follows infection, and deliberate induction of sores on unexposed parts of the body has long been practiced in the Middle East to avoid the disfigurement of exposed scars. Transmission can be effected by direct contact, fomites, and houseflies, but the principal spread is undoubtedly by sandflies in a manner similar to that in kala-azar. Oriental sore occurs in southern Asia, southern Russia, the Near East, equatorial Africa, and the Mediterranean region, the principal vectors being P. sergenti, P. papatasii, and, probably, P. caucasicus. Laboratory diagnosis is made by identification of the parasites in stained smears of scrapings from the lesions. Reliable diagnosis of oriental sore has been reported with an intradermal test. Since it is often very difficult to detect parasites in the lesions, such a procedure would be valuable. Local or systemic administration of antimony compounds such as Neostibosan is usually effective in treatment.

Leishmania braziliensis. Morphologically this species is indistinguishable from *L. tropica* and *L. donovani*, and its primary lesion closely resembles that of *L. tropica*. ⁵⁴ Superficial granular or moist ulcers may

occur at any skin site. In some endemic areas the parasite characteristically migrates to secondary foci, particularly mucocutaneous junctions, causing extensive destructive erosion of the nasopharynx, larynx, and associated structures, with facial disfigurement. Metastatic lesions occur with probable spread through the lymphatics and leishmanias have been recovered from the peripheral blood. Diagnosis and treatment are the same as used for the other leishmanias, by recovery and identification of the parasite in stained smears from lesions. An intradermal test, the Montenegro reaction, utilizing an antigen derived from cultured leishmanias is also of value. The disease is known by a variety of names throughout its range, including uta, espundia, chiclero ulcer, and mucocutaneous leishmaniasis and has a distribution ranging from Argentina north into The Yucatan peninsula of Mexico. In Central America, cutaneous leishmaniasis is a sylvatic disease, having reservoir hosts. such as small rodents and other forest animals. In South America the infection has been described from dogs.88

SPOROZOA

Malarial parasites. With the exception of an uncommon intestinal parasite, the only sporozoa infecting man are the malarial parasites. They were first recognized by Laveran in 1880, and the life cycle in human erythrocytes was described by Golgi. Manson's suggestions led Ross to the demonstration in 1898 of mosquito transmission of avian malaria, and Grassi, Bignami, and Bastianelli later in the same year showed the mechanism of spread of human malaria. Man harbors four species of malarial parasites, of which *Plasmodium vivax* will serve as an example. ¹³

Characteristics and life cycle. In fresh preparations of infected blood the parasites of *P. vivax* appear as clear areas in the erythrocytes. They contain yellow or brown granules of pigment, a digestion product of hemoglobin which has been identified microchemically as hematin. In blood films colored with stains such as Giemsa the parasites show blue cytoplasm and violet red nuclei.⁴⁷ The earliest stage in the erythrocyte, the *ring* stage, consists of a thin ring of cytoplasm with a nucleus at one side. The parasite grows, becoming an irregular uninucleate body containing several brown pig-

ment granules. This stage is known as the ameboid trophozoite. The parasitized cell has now enlarged somewhat and may show scattered throughout its cytoplasm minute red granules, "Schüffner's dots," which are apparently a result of injury to the cell. The parasite continues to grow, phagocytizing the erythrocyte hemoglobin which it digests, thereby accumulating more pigment. Eventually it nearly fills the erythrocyte, which is now about one and one-half times its normal diameter. The nucleus divides repeatedly until 12 to 24, usually about 16, nuclei are present. This is the schizont stage. Finally, in the *segmenter* stage, the cytoplasm divides, a portion surrounding each nucleus. The pigment is left in a dense clump, and the cell disintegrates to release the daughter cells, or merozoites, into the plasma. Here they invade fresh erythrocytes and repeat the cycle. The above process of growth and multiple fission is known as schizogony. It occupies, in P. vivax, about 48 hours, and the growth is regulated by the daily cycle of activity of the host, so that segmentation usually occurs at about the same time every other day.

After several schizogonic cycles a difference may be noted in the infection. Some ameboid stages, instead of becoming schizonts and undergoing asexual reproduction, develop into large uninucleate parasites with scattered pigment granules. These are the sexual stages. The female, or macrogametocyte, shows a compact, dark red nucleus and intense blue cytoplasm. The male, or *microgametocyte*, has a more diffuse, less deeply stained nucleus, and the cytoplasm is paler, often pinkish rather than blue. The gametocytes undergo no further development in man, eventually degenerating or being destroyed unless they are taken up by a susceptible mosquito.

In the stomach of the mosquito, gametes are produced. The macrogametocyte escapes from the erythrocyte and becomes a single macrogamete, corresponding to a metazoan ovum. The microgametocyte produces at its surface, by a process generally called "exflagellation," four to eight long, whip-like microgametes, counterparts of the spermatozoa of higher animals. One of these actively wriggling microgametes fertilizes a macrogamete. The resulting spherical zygote⁷² on the surface of the blood meal becomes entrapped between the contracting epithelial cells of the mosquito

stomach as the meal is digested. Growth results in an oöcyst which comes to rest on the outside of the stomach. Other authors believe that a fusiform oökinete is formed which actively penetrates the epithelial cells. The above process in the mosquito occupies one to two days. Nuclear multiplication occurs and the oocyst grows until a diameter of about 50 μ is attained. The oöcyst now contains many hundreds of nuclei. Each acquires a bit of cytoplasm and becomes a spindle-shaped body, about 8 μ long, the sporozoite. With the rupture of the oöcyst, these sporozoites scatter throughout the body of the mosquito. Many accumulate in the salivary glands, where they are injected into man by the biting mosquito. The complete development in the mosquito requires from one to two weeks: 25° C. is said to be the optimal temperature, no development occurring below 15° C. nor above 30° C.

For many years it was believed that the sporozoites entered erythrocytes to initiate the schizogonic cycle described above. Indirect evidence suggested that the parasites underwent a different type of development before invading the blood. This development was first discovered in a malarial infection of birds.⁷⁴ The sporozoites were found to enter fixed tissue cells where, as cryptozoites, they undergo a type of schizogony fundamentally like that in erythrocytes except that no pigment is produced. Segmentation produces merozoites which invade new macrophages and repeat the cycle. Some of the second generation merozoites enter erythrocytes to establish the blood schizogony. Others continue to reproduce in tissue cells as exoerythrocytic stages, probably throughout the whole course of infection, and may repeatedly give rise to new schizonts in erythrocytes. The cryptozoites and later exoerythrocytic stages are resistant to drugs effective against the blood parasites.14

Until 1948 neither cryptozoites nor later exoerythrocytic stages had been observed in mammalian malarias. They were observed first in monkey malaria and later in a human volunteer infected with enormous numbers of sporozoites of *P. vivax*. Large schizonts were found in the liver five to 10 days after sporozoite inoculation. Unlike those in avian malarias, which occur in macrophages, the cryptozoites in *P vivax* were said to be in hepatic cells. The parasites observed ap-

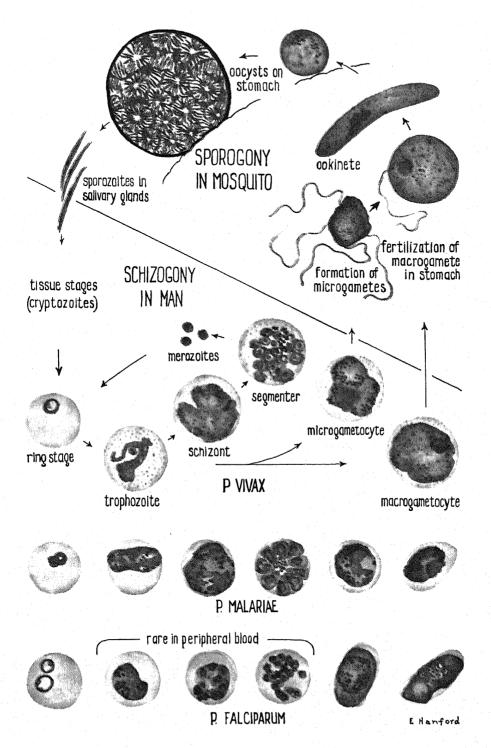

Figure 235. Life-cycle and comparative morphology of the malarial parasites of man. Oöcysts, × 600; remaining stages, × 2000. (Schizogonic stages redrawn from Huff: Manual of Medical Parasitology.)

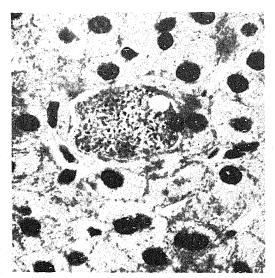

Figure 236. Cryptozoite of *Plasmodium vivax* in liver section. (Courtesy of Col. H. E. Shortt.)

pear to constitute a second generation of reproduction, but no organisms have been observed before the fifth day of infection.

In experimental infections with simian malaria, schizonts have been observed in the liver three and one-half months after infection, indicating persistence of the tissue parasites during and after the acute blood infection. Knowledge of various aspects of the exoerythrocytic cycle of plasmodia of all vertebrates is fully covered in a monograph by Bray¹⁴ and the more recent literature is covered by Eyles.³⁸

While much study is still required in this very important aspect of malaria, it is now possible to reconstruct in essence the development of infection in *P. vivax*. Sporozoites initiate a type of schizogony similar to that described above for avian malarias. In *P. vivax*, however, at least part of this cycle seems to be in cells other than macrophages. After about nine days some of the merozoites initiate the erythrocytic schizogony. Others apparently continue the exoerythrocytic infection, which can later give rise to new generations of erythrocytic parasites.

Limited success has been achieved in the artificial cultivation of malarial parasites. Geiman observed several generations of reproduction with *P. vivax* in erythrocytes in vitro. ⁵⁵ An avian plasmodium has since been maintained for 10 passages over a period of 18 days. Some growth has also occurred in a noncellular medium contain-

ing a lysate of erythrocytes.¹⁵⁰ A good deal of physiological information has come from these studies, but practical cultivation for routine work has not been obtained. Exoerythrocytic stages of avian malarias have been grown in tissue cultures of macrophages, and various cells derived from chick embryo heart, and chick meninges. Phase photocinematography of cultures are showing hitherto unsuspected morphological features of the exoerythrocytic schizonts and merozoites as well as providing information on motility and the mechanisms of cell invasion.⁷⁵

The life cycles and morphology of the other human malarial parasites in erythrocytes are fundamentally similar to those of P. vivax. P. malariae requires 72 hours for the completion of schizogony. The erythrocytic parasites show several differences of diagnostic value. No granules of the type of Schuffner's dots are seen in the infected cells. The cells are not enlarged during growth of the parasites. The older trophozoite is not ameboid like that of P. vivax but commonly exhibits a "band" form across the parasitized cell. The segmenter produces six to 14, usually eight, merozoites, arranged in 'a "rosette" form. The gametocytes are small, and the pigment typically occurs in abundant, large dark granules, the optimal temperature for sporogony in the mosquito is said to be about 22° C., and sporogony is slow, requiring three weeks or more.

P. falciparum, like P. malariae, causes no enlargement of the infected cells, but some parasitized cells show granules, Maurer's dots, which correspond to the Schüffner's dots of P. vivax. Schizogony results in six to 24 merozoites. The schizonts and segmenters typically accumulate in capillaries of internal organs, appearing in the peripheral blood only in very heavy infections. Normally, therefore, only ring stages and gametocytes are seen in blood films. Infection of erythrocytes by two or more rings is common and the rings often contain two nuclei. The gametocytes are distinctive, exhibiting a characteristic sausage shape which distorts or obliterates the infected cell. Because of their shape, they are commonly called "crescents." pigment is finely granular or amorphous in appearance and in the gametocytes it is typically concentrated about the nucleus. The optimal temperature for sporogony is said to be 29° C.

P. ovale is a rare species showing similarities to both P. vivax and P. malariae but characterized chiefly by the fact that the infected cell is often distorted into an oval. Its significance is not known, although many investigators consider it an aberrant type of P. vivax.

Malaria. Vivax malaria, or benign tertian malaria, is featured by typical chills and fever occurring at the time of segmentation of the peripheral blood parasites. These paroxysms begin with an acute, shaking chill while the temperature is rising. A "hot stage" occurs at the fever peak, the patient feeling unbearably hot and the oral temperature usually reaching 104° or 105° F. This gives way to a "sweating stage" during which the fever falls rapidly to normal or slightly below. Parasite products or red blood cell contents released at disruption of the infected cells are presumably responsible for the paroxysm. Paroxysms coincide, as stated above, with the time of parasite segmentation. Hence they occur every 48 hours if all the parasites reproduce on the same day. Often, however, distinct broods of parasites segment on alternate days. Vivax malaria commonly show quotidian (daily) chills for several days followed by the suppression of one brood of parasites with resultant tertian chills (every other day). Between paroxysms the patient feels and appears normal.

Significant anemia occurs commonly in vivax malaria but is rarely serious unless other factors are involved. A week or more after the beginning of an attack, particularly in children, the spleen usually enlarges and remains enlarged for two to six months after termination of the attack. The untreated attack typically lasts three to six weeks, often with temporary cessations of clinical activity. It is followed by a period of latency during which parasites cannot be found microscopically in the peripheral blood. During part of this time large transfusions of blood from the infected person fail to induce infection in recipients. This suggests that exoerythrocytic stages are responsible for maintenance of infection during latency. In many cases renewal of clinical activity, or relapse, occurs after two to 10 months of latency, the clinical picture resembling that in the primary attack. The infection usually dies out after two to three vears, and no further relapses occur.

Malaria due to P. malariae is known,

because of the 72-hour cycle of reproduction, as quartan malaria, the chills occurring every third day. It is basically similar to vivax malaria, though the paroxysms are often more severe. The incubation period is usually long, three weeks or more, and the period of clinical activity typically lasts for several months. Relapses are uncommon, but latent infection may persist for many years, as shown by the occasional development of quartan malaria in recipients of blood transfusions from persons who have not shown evidence of infection for 30 years or more.

Falciparum malaria is widely-known as malignant tertian or estivo-autumnal malaria. As noted above, P. falciparum is characterized by accumulation of schizogonic stages in internal organs. As a result, in addition to or instead of the typical paroxysms, which are quotidian or tertian, various local manifestations of the disease may be prominent. This is especially true in the tropics, where such "pernicious" malaria may follow a series of typical chills. The most common types are algid (cold) malaria, gastrointestinal manifestations, and cerebral malaria with coma and often death. These peculiarities of falciparum malaria make it the cause of most of the deaths attributable to human malarial infection and an important factor in many deaths traced to other diseases. Blackwater fever, a dangerous hemoglobinuria, is associated with falciparum malaria and is thought to be an occasional late effect of repeated infection. P. falciparum infections rarely relapse and rarely persist more than a year or two. It is believed that the exoerythrocytic stages do not persist after the cycle in erythrocytes has begun.

IMMUNITY. Malaria exhibits acquired immunity. After recovery from an acute attack, the individual is highly resistant to superinfection with a strain similar to that already present, but the resistance lasts for at most a few months after elimination of parasites from the body. This immunity depends on active phagocytosis and digestion of parasitized erythrocytes by the macrophages of spleen, liver, bone marrow, etc. That the parasitized cells are sensitized by antibodies is suggested by the fact that serum from recovered animals partially protects against infection. The immunity to superinfection is species- and strain-specific. During latency the parasites apparently

continue to reproduce by exoerythrocytic shizogony, sporadically producing blood parasites which are held in balance by the acquired immunity. Relapse occurs when this balance is disturbed, permitting the blood parasites to increase greatly in numbers. The factors are little known, though it has been shown that operations increasing blood sugar induce relapse in avian malaria.

Different strains of vivax malaria exhibit characteristic patterns of activity. Thus, an American strain typically relapsed about 10 months after the initial infection, while a strain from New Guinea usually relapsed within two months. Data such as these indicate that reactivation of latent malaria is at least partly determined by inherent cyclic properties of the parasites. The lesser susceptibility to, as well as the lessened severity of infection of, the negroid race to P. falciparum and P. vivax is cited as an example of racial immunity (Chap. Nine). Possession of the inherited sickle cell trait also confers a degree of immunity to P. falciparum as the erythrocytes are deficient with respect to the needs of the parasite. The maximum parasite count in those posessing the trait is much less than normal; the malaria mortality is less, resulting in the maintenance of a high population frequency of sickle cell anemia in some areas of P. falciparum endemicity. 104, 154

Partial inhibition of avian and monkey malarial infections has been achieved with killed vaccines. There is no evidence concerning human malaria, but, because of the nature of immunity to malaria, it seems unlikely that vaccination would be of practical value. Serum agglutination of parasitized cells or isolated parasites has been reported in experimental infections. It is species- or strain-specific. Complement-fixing antibodies occur in the serum and are group-specific, reacting with extracts of avian and simian malarial parasites as well as with those from man.

Diagnosis. Laboratory diagnosis of acute malaria rests on the finding of parasites in peripheral blood films. They are most easily identified in thin films stained with Giemsa, but, since parasites are often scanty in the peripheral blood, dehemoglobinized thick films, similarly stained, are widely used. The rapid staining method of Field⁴⁷ is of especial value for such preparations. The fact that parasite morphology is ab-

normal in thick films is offset by the much greater volume of blood which can be examined in a comparable time. In surveys the characteristic spleen enlargement is a nonspecific but highly suggestive indication of current or recent malarial infection. Because it usually persists for several months it affords a more stable index of the infection rate in an area than do clinical or parasitological surveys.

CHEMOTHERAPY. Treatment of malaria for centuries depended on the bark or extracts of the bark of cinchona trees. The main active principle in cinchona bark is the alkaloid quinine. Quinine neither prevents nor cures the natural infection but rapidly suppresses the number of blood parasites below the density necessary to produce symptoms. The synthetic drug quinacrine (Atabrine) has similar action, and in addition it can cure falciparum malaria. Chloroquine and Camoquin, developed in large-scale World War II research, have properties like those of quinacrine but are more effective.28 Paludrine, a product of British wartime research, is a very effective suppressive for vivax malaria and is both prophylactic and curative for P. falciparum infection. The distantly related Daraprim (pyrimethamine) has similar but stronger action. These two drugs suffer from the disadvantages that they act slowly and that the parasites may become resistant to them.

The above drugs taken continuously during exposure to vivax malaria act as suppressives, holding the infection down to subclinical levels. They do not prevent or cure the infection. *Primaquine*, however, destroys the exoerythrocytic stages and if given prior to invasion of the erythrocytes will prevent clinical malaria from occurring. It is also used in conjunction with drugs effective against the erythrocytic stages to cure established vivax infection, since elimination of the persistent exoerythrocytic stages is mandatory to prevent relapse.^{27, 117}

An exciting "repository" chemotherapeutic agent has been tested in a small series of men exposed to sporozoite and bloodinduced *P. vivax* infection. A single intramuscular injection of this dihydrotriazine metabolite of chlorguanide (Cl-501) protects against repeated infection for a minimum of seven months.^{29, 148}

As with other microorganisms, inheritable drug resistance can be induced in the plasmodia. 11,61 Development of pyrimeth-

amine resistance in both *P. vivax* and *P. falciparum*¹⁷² has been observed on a number of occasions, and particularly virulent strains of Chloroquine-resistant *P. falciparum* have been recovered in Colombia and Thailand.¹⁷³ The former retained sensitivity to pyrimethamine but the latter is resistant to pyrimethamine but Atabrine sensitive.

Epidemiology and control. Malaria is the most common infectious disease of man. occurring throughout the warmer regions of the world and extending well into the temperate zones to occupy a large part of the land area between 60° N. and 40° S. latitude. The principal factor in distribution of the infection is climate, which affects both the distribution and abundance of the mosquito hosts and the development of the parasite in the mosquito. The human malarial parasites are not found in lower animals. Man is, therefore, the only reservoir of infection. Racial immunity is known in the case of P. vivax. Negroes are less readily infected with most strains than whites and seldom show symptoms. Local populations with high natural immunity to P. falciparum have also been reported. Age resistance is not known, but in endemic regions clinical malaria may be rare in native adults who have been constantly reinfected with the local strains of parasites.

Barring rare congenital cases, blood transfusions, 12 and accidental transfers of blood, as by drug addicts sharing contaminated syringes, human malaria is transmitted exclusively by the bites of certain mosquitoes of the genus Anopheles. This genus, comprising some 200 species throughout the world, is readily distinguished from the common house mosquitoes of the genera Culex and Aedes by several characteristics. The adult generally rests at an angle to the surface, with proboscis, head, and body in a straight line, whereas the others rest parallel, with the head and proboscis turned down. The wings are usually spotted, those of other mosquitoes being unmarked. The palps of the female are as long as the proboscis, giving the impression of three long appendages from the head in addition to the antennae, whereas the other genera have short, barely noticeable palps. The eggs bear inflated floats and are laid singly on the water, whereas in Culex they are laid in rafts on the water and in Aedes they are deposited singly on damp surfaces. The

larvae of Anopheles lie flat at the surface of the water, feeding on floating particles, while those of other genera hang down in the water from an elongated breathing tube and usually feed on the bottom.

Only the female mosquitoes feed on blood, most Anopheles biting at dusk or in the night. The breeding places vary greatly in character, almost any type of water collection serving to support the larvae of one or more species of Anopheles. Most species, however, are quite specific in the types of water collections they choose. The principal malarial vector in the southeastern United States, Anopheles quadrimaculatus, breeds chiefly around the debris- and weed-covered edges of swamps, ponds, and sluggish streams. Important malarial vectors, however, are found in hill streams (A. minimus in Southern Asia), brackish marshes (A. atroparvus in Europe), small temporary pools (A. gambiae in Africa), water held in plants growing in the tops of trees (A. bellator in Trinidad), etc.

Not all species of Anopheles serve equally efficiently as vectors of malaria, about 75 being considered dangerous carriers in one or more regions. The chief determining factors are abundance, contact with man, and susceptibility. The last varies greatly among species and among populations within species. Little is known of the factors in human malaria, but simple genetic differences have been shown to determine susceptibility of some Culex mosquitoes to avian malaria. In most situations which have been adequately studied, contact with man is the principal factor in the importance of species of Anopheles. Several susceptible species are abundant in the southeastern United States, but in most of this area only one, A. quadrimaculatus, shows sufficient preference for human blood to serve as an important carrier. In Europe species (formerly lumped together as A. maculipennis) distinguishable only by morphology of the egg differ so greatly in their relative preferences for human and animal blood that some are dangerous vectors while others, equally susceptible, are insignificant in the spread of malaria.

Malaria control rests largely on the interruption of the mosquito phase of the life cycle. This may be accomplished by reduction in mosquito numbers or prevention of contact between mosquitoes and man. If mosquito reduction is to be attempted, the

Caluar and bowering males

differences in relative importance of different species, or even of the same species in different regions, require that the principal vectors in a given area be determined before control is attempted. Such determination is of value in avoiding waste of resources on unimportant mosquitoes. Furthermore, unplanned control efforts may completely miss the principal vectors and have even, on occasion, made matters worse by favoring the breeding of dangerous species. The "natural index" of infection, determined by examining stomachs and salivary glands of wild-caught female mosquitoes for occysts and sporozoites of malarial parasites, is the best guide to relative importance of a species. Unfortunately, the figure is often so low that dissection of large numbers of mosquitoes is required. In such cases expediency may justify indirect measures. Susceptibility may be determined by exposure of laboratory-reared mosquitoes to carriers and dissection of the fed females for stages of the parasite ("experimental index"). Contact with man may be measured by the location of resting mosquitoes (e.g., in houses as against stables) or by precipitin tests on fed mosquitoes to determine the type of blood they contain.

If control is to be applied to the breeding of mosquitoes, the habits of the important vectors in an area must be determined. Elimination of breeding places is the method of choice in many regions. Water collections may be destroyed by drainage or filling. Salinity may be controlled by tide-gates. Breeding around the margins of reservoirs may be eliminated by water-level fluctuations. Shade may be increased or decreased by control of vegetation. Streams may be cleared or periodically sluiced. Specific methods, it will be obvious, depend on local conditions and the habits of the mosquitoes involved. Several effective poisons (larvicides) are available for attack on the aquatic stages. Oils sprayed on the water surface are toxic to the eggs, larvae, and pupae. DDT in oil is extremely effective. A minor method of local value is the stocking of ponds and pools with top-feeding minnows. Gambusia or Lebistes, which eat mosquito larvae.

Attack on adult mosquitoes, formerly a secondary measure, is now the most important technique for malaria control. The insecticides, DDT, lindane and dieldrin, have given malariologists a weapon of tremendous value. Sprayed on walls, screens, etc., they

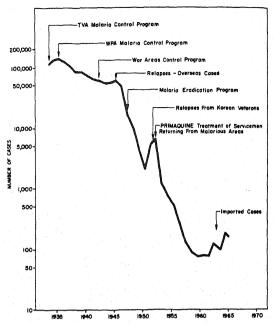

Figure 237. The incidence of malaria in the United States as indicated by the cases reported during the period 1933-1965. (Morbidity and Mortality Weekly Report, Annual Supplement, Vol. 14, No. 53. Communicable Disease Center, Public Health Service, U.S. Department of Health, Education, and Welfare.)

kill adult mosquitoes which rest on these surfaces, even several months after application. For those species of Anopheles which enter houses to bite man, these insecticides have already demonstrated their value as an inexpensive and highly effective tool in malaria control. Malaria is no longer endemic in the United States and only sporadic cases of exotic origin are found today. The success of the control of malaria here and in several other areas, along with the development of better chemotherapeutic agents and economically feasible residual sprays, has led to the hope that world-wide malaria eradication will soon be an accomplished fact. 124 Detailed protocols and plans for this have been prepared. 112 However, in addition to the factors previously known, the problem has become further complicated by the development of plasmodia resistant to chemotherapeutic agents. This has become particularly evident in the strains of Plasmodium falciparum from various areas in southeast Asia resistant to chloroquine and other synthetic antimalarials.118 Another complication has been the development of insecticide resistance in anophelene mosquitoes. At the end of 1958 only three re-

sistant species were known and in the following year an additional 14 species of anophelene mosquitoes resistant to dieldrin and/or DDT were described.103 More recently another complicating factor has been found in a vivax-type malaria of macaques transmissible to man. Accidental transmission via mosquito has been recorded and further experiments indicate its ability to produce clinical malaria in man. Two strains of this parasite, Plasmodium cynomolgi, have been transmitted from man to man by mosquito. 10, 30, 135 The failure of control and eradication programs coupled with the continuing importance of malaria in military operations has caused a resurgence of basic research after an inactivity of almost 15 years. 130

Malarial parasites of lower animals. Malarial parasites fundamentally like those of man occur in apes, monkeys, bats, rodents, birds, and lizards. Since lower animal hosts are not readily infected with the human malarial parasites, the natural parasites of monkeys, birds, and, recently, rodents have been widely used experimentally. The species most widely studied are P. brasilianum, P. knowlesi, and P. cynomolgi of monkeys, P. cathemerium, P. relictum, P. gallinaceum, and P. lophurae of birds, and P. berghei of rats and mice. 53

INTESTINAL SPOROZOANS

Two species of coccidia, Isospora hominis and I. belli, are sporadic infectors of man although cosmopolitan in distribution. A resistant oöcyst is passed in the stools and infected individuals have slight to severe diarrhea. No information on the life cycle, therapy, or epidemiology is available and it is assumed that these species parasitize the epithelial cells of the small intestine as they do in the related species found in the dog and cat. The organisms have been described most frequently from the tropics and subtropics and have caused epidemics in military forces in the southwest Pacific islands during World War II. 45

PARASITES OF UNCERTAIN AFFINITIES

Toxoplasma gondii. Toxoplasma gondii was discovered in 1908 in rodents by Nicolle

and Manceaux in Africa and by Splendore in Brazil. The first clearly recognized human case of disease due to this parasite was reported by Wolf and Cowen in 1937. 128, 163

The organism is usually included with the sporozoa as a special group along with sarcocystis, with which it shares some characteristics. Some authors question their inclusion within the protozoa. Reproduction is asexual with cysts or pseudocysts containing naked trophozoites. Only a single host is required (monoxenous) and locomotion is by gliding or flexing of the cell, as no locomotor organelles are present.

Characteristics and life cycle. The trophozoite is a crescentic or oval body, 5 to 7 μ by 2 to 4 μ in size, staining blue with a reddish nucleus in Giemsa preparations as shown in the accompanying figure. It reproduces by binary fission in living cells. A great variety of cells are susceptible, but those chiefly infected are macrophages and other connective tissue cells, smooth and cardiac muscle, neurons, and microglia. While the parasites reproduce only in cells, they are often found free in body fluids.

In chronic infections they occur in a pseudocyst stage. This consists of a cluster of parasites resembling the trophozoites surrounded by an irregular wall. The origin of this wall is not known, but it may be the remains of a host cell in which the parasites proliferated. The pseudocysts are most abundant in the brain and skeletal muscle. They appear to be resting stages, more resistant than the reproductive forms.

Toxoplasma have not been cultivated in

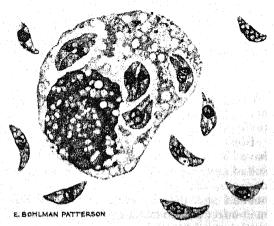

Figure 238. Toxoplasma gondii, free and in cell, from mouse brain smear. Giemsa, Camera lucida; approx. × 2000.

artificial mediums. They grow readily in tissue cultures of various types, including HeLa cells, and in chick embryos.

Toxoplasmosis. Although infection with T. gondii is very common in man, it rarely gives rise to acute disease. Most of the clinical cases occur in newborn infants infected congenitally during late fetal development. The active lesions predominate in the central nervous system and eyes, causing blindness, gross defects of the brain, and, not infrequently, death. Infection of adults is usually subclinical, but pneumonitis, enlargement of lymph nodes and spleen, fever, and a maculopapular rash may be exhibited. A severe chorio-retinitis may result from infection of the eyes. 113

Recovery is apparently accompanied by immunity to reinfection, although the pseudocysts, at least in lower animals, may persist for long periods in the tissues. Most experimental animals show solid immunity to reinfection. Monkeys and man exhibit a thermolabile antibody which protects rabbits against characteristic skin lesions resulting from the injection of toxoplasma.

Laboratory diagnosis requires isolation of the organisms or immunological tests. In neonatal cases it is usually possible to demonstrate the organisms by inoculation of laboratory animals. While all mammals and birds tested have been found susceptible, mice are preferred for isolation of the parasites because they are free from natural infection. Complement fixation may be used, but the most reliable immunological test is the dye inhibition reaction of Sabin and Feldman. This depends on the fact that toxoplasma in the peritoneal exudate of mice stain well with alkaline methylene blue in normal serum but not in immune serum. An accessory factor, present in fresh normal serum but destroyed by heat or by storage. is essential to the reaction. The test becomes positive two weeks or more after onset, reaching a titer of 1:256 or higher, and remains positive for many years. Fluorescent antibody methods have also been shown to be of diagnostic value.

Both acute and subacute toxoplasmosis have been treated with combinations of sulfadiazine and pyrimethamine. Treatment destroys the parasites in experimental animals and, though beneficial in some human infections, toxic side effects may occur with irreparable damage to the brain and eye.⁵⁰

5 7 7 7 7 Mag

Epidemiology. Perhaps the most vexing question occupying investigators of toxoplasmosis is the method or methods of natural transmission. It is clear that congenital infection of human embryos can occur, but it is equally clear that other routes of infection exist. The parasite is extremely abundant in nature. Surveys with the dye test show that up to 60 per cent or more of human populations have been infected. Investigations in various parts of the United States have revealed past infection rates of 17 to 35 per cent, with rates of over 65 per cent in the age group above 40. A wide variety of wild and domestic birds and mammals show evidence of infection, often with high incidence. Human congenital infections have been associated with home environs in which mice and other vertebrates had abnormally high incidences of infection.³⁹ The pseudocysts in muscle are infective by mouth, and epidemiological evidence suggesting that infection might be acquired from undercooked pork has been reinforced by the finding of viable toxoplasma in samples of meat from 22 per cent of hogs from one slaughterhouse. However, orthodox Jews sometimes show evidence of a high incidence of infection, and some species of herbivorous animals are commonly infected, so it is obvious that pork or other meats are not the only important sources of infection. Toxoplasmosis should be regarded as one of the zoonoses in which man is only one of a relatively large number of natural hosts. Recently it has been demonstrated that parasitic nematodes (Toxocara) are capable of transmitting toxoplasma.78 The evidence suggests that the toxoplasma is transmitted within the nematode egg, and is liberated with or within the larval worm on hatching in the intestine of a warm-blooded host.

Sarcocystis. A single genus has been described with numerous species commonly found parasiting the muscles of mammals, birds, and reptiles. They are extremely common in ruminants, occasionally producing a severe pathology in sheep. Sarcocystis lindemanni, the species reported in a number of instances infecting man, is not known to produce detectable symptoms. The organisms are fusiform tubes, round in section, up to several centimeters in length and usually in striated muscle. These "Meischer's tubes" have a hyaline wall. Internally they are divided into compartments containing many thousands of sickle-shaped individ-

Manager and a second

uals 12 to 16 μ in length. Experimentally, infection may be accomplished by ingestion of infected meat.

Pneumocystis carinii. Infection with Pneumocystis is associated with highly contagious, epidemic, infantile, interstitial, plasma-cell pneumonia. The organisms are ovoid or crescent-shaped, 1 to 3 μ in diameter, and are commonly seen in rosettes of eight individuals within a membrane.

free or within phagocytes. The organism is considered to be a protozoan and the etiological agent of the disease, which in young infants frequently terminates in death. It has also been described from a wide variety of wild and domestic mammals. Although widely distributed, infection is but rarely diagnosed. Pentamidine and supportive measures have resulted in excellent decreases in mortality.⁷⁹

The Metazoa

All phyla of animals other than protozoa are commonly designated by the term Metazoa, and it will be convenient to mention certain general characteristics of the parasites of man, mostly known as "worms," which belong to this aggregate. They are usually macroscopic in size, ranging from about a millimeter to several meters in length. Their structure is generally complex. and their life cycles vary from the simple production of infective eggs or larvae to complex alternation of generations involving as many as three different hosts. An important general characteristic is that multiplication usually does not occur in the human body, so that infection does not increase in intensity in the absence of re-exposure. Until recently, true cultivation of worms parasitic in vertebrates had not been achieved. The great variety of metazoan parasites of man makes it impossible to discuss them extensively in a small space. Therefore, representative examples will be used wherever possible. For fuller discussions the reader is referred to the general texts cited earlier.

PLATYHELMINTHES

The phylum *Platyhelminthes*, or "flatworms," is differentiated from other phyla of animals by several characteristics. They are bilaterally symmetrical and composed of the three primitive germ layers of tissues—ectoderm, endoderm, and mesoderm. The body cavity is not lined with mesoderm, as in higher forms, but filled with a spongy mass of cells, the *parenchyma*. The digestive tract is absent or, if present, lacks an anus, solid wastes being regurgitated

through the mouth. There are three major classes—the Turbellaria, which are free-living forms or external parasites of aquatic animals, exemplified by Planaria; the Trematoda, or flukes, which are all parasitic; and the Cestoda, or tapeworms, also all parasitic.

TREMATODA

The human lung fluke, Paragonimus westermani, and the blood fluke, Schistosoma mansoni, will serve as examples of the trematodes.

Paragonimus westermani. The adult worm, found by Westerman in 1877 in the lungs of a tiger, was described by Kerbert in 1878. Nakagawa, Yokogawa, and others elucidated the life cycle. Several species have been described, differing but little in their morphology, and some authors believe that there is only one species parasitizing man, *P. westermani*. 1711

Characteristics and life cycle. The adult lung fluke is an ovoid reddish worm, 7 to 12 mm. long by 3 to 6 mm. in diameter, covered with a transparent cuticle which is studded with spines. The anatomy of a flattened specimen is shown in Figure 239. Two muscular suckers are present, one on the ventral surface, the acetabulum, the other at the anterior end, the anterior sucker, perforated by the mouth. The mouth opens into a muscular pharvnx, followed by a thin esophagus. This divides into two blind intestinal ceca extending down the sides of the body. The nervous system is simple, and no special sense organs are present. The excretory system consists of a bladder opening at the posterior end and receiving collecting tubules which extend throughout the body, terminating in characteristic

"flame cells." The circulatory system is rudimentary, consisting of indefinite channels through the parenchyma.

The adult fluke is hermaphroditic, both male and female reproductive systems occurring in the same individual. These systems are typically elaborate and, as in most flukes, are the most prominent structures of the body. In the female system a single ovary connects via an oviduct with the oötype, where the eggs are formed and receive their shells. In its course the oviduct receives the common vitelline duct, into which shell material comes from the branched vitellaria, glands occupying the sides of the dorsal surface of the body. The oviduct also has a diverticulum, the seminal receptacle, in which sperms are stored. An inconspicuous duct of unknown function, Laurer's canal, runs from the oviduct to an opening on the dorsal surface of the body. The oötype, surrounded by gland cells, Mehlis' gland, opens into the uterus, a long coiled tube which carries the completed eggs to the common genital pore near the acetabulum.

The male reproductive system consists of paired testes in the posterior part of the body, connecting by vasa efferentia with the vas deferens, which empties into the common genital pore along with the uterus. Part of the vas deferens is widened into a sperm reservoir, the seminal vesicle, and a more distal portion is the glandular prostatic region. The terminal portion forms a muscular copulatory organ, the cirrus.

The eggs produced by adult worms in the lung are coughed up and either escape in the sputum or are swallowed and passed in the feces. They are ovoid, averaging 60 by 90 μ in size, and show a removable cap. the operculum, at one end. The embryos are undeveloped at the time of escape from the host. They develop in from two to six weeks in water, where the eggs hatch by the opening of the operculum to release a free-swimming ciliated larva, the miracidium. This larva survives only a few hours unless it succeeds in penetrating the tissues of a suitable intermediate host. Various snails of the genera Melania and Pomatiopsis can serve as hosts. In the lymph spaces of the snail the miracidium becomes an irregular, thin-walled sac, the sporocyst, growing to a final length of about 0.4 mm. Cell masses within the sporocyst enlarge, developing in about one month into 12 or more rediae. These escape by rupture of the sporocyst and grow to a length of about 0.3 mm. They differ from the sporocyst principally in having a rudimentary digestive tract and a birth pore. By a reproductive process similar to that in the sporocyst the first generation redia produces 12 or more second generation rediae. These escape by way of the birth pore and grow to a length of about 0.5 mm. Within each second generation redia arise 20 or more tailed larvae. or cercariae. The cercaria is essentially a rudimentary adult worm. It differs principally in having a small tail and two types of penetration organs, a stylet in the mouth region and several gland cells, opening at the anterior end, which secrete histolytic enzymes. About three months after invasion of the snail by miracidia the cercariae escape and move about in the water, dying in one or two days unless they find a suitable second intermediate host, a crayfish or crab of any of various genera, especially Astacus and Potamon.

The cercaria penetrates the softer part of the integument of a crab, loses its tail and grows in the tissues into the *metacercaria*, a near-spherical body about 0.4 mm. in diameter enclosed in a cyst wall. The full development requires about one month, after which the metacercaria is infective when eaten by man. In the small intestine the cyst wall softens, releasing the metacercaria, which penetrates the wall of the small intestine and reaches the abdominal cavity within a few hours. It wanders rather aimlessly but usually passes through the diaphragm within a few days and invades the lung, where it becomes encapsulated by the tissues and grows to the adult stage. Considering this apparently random migration it is interesting to note that the pleural cysts commonly contain two or three adults. After about six weeks eggs may be found in the sputum.

Paragonimiasis. The adult worms in the lung, and particularly the eggs they produce, cause tissue destruction, inflammation, and hemorrhage. Local pneumonic processes with cough and bloody sputum are characteristic. As in most worm infections, the damage is roughtly proportional to the nul ber of organisms present. In severe case, weakness and even death may result from the extensive lung injury. Aberrant worms in other tissues, such as the brain, may produce local injury.

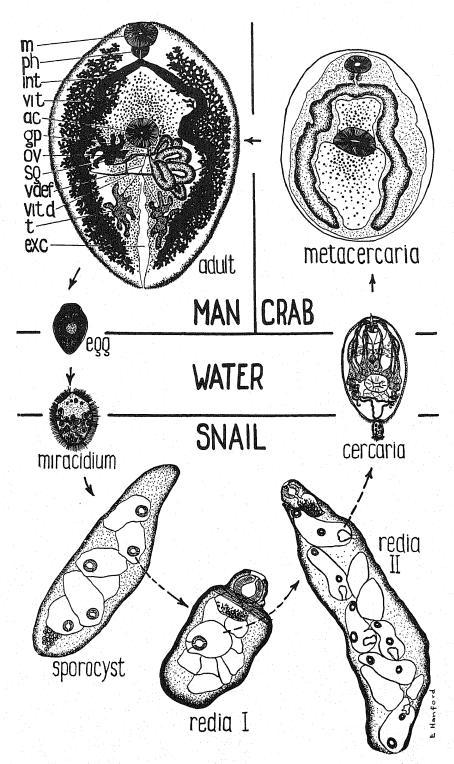

Figure 239. Life cycle and morphology of Paragonimus. m, mouth; ph, pharynx; int, intestinal cecum; vit, vitellaria; ac, acetabulum; gp, genital pore; ov, ovary; sg, oötype; vdef, vas deferens; vitd, vitelline duct; t, testis; exc, excretory bladder. There is no evidence concerning acquired immunity to Paragonimus. Human infections have been shown to persist at least six years in the absence of re-exposure, but it is said that they often clear up after several years.

Diagnosis of lung fluke infection depends on the finding and identification of characteristic eggs in the sputum or feces. As in other trematode infections, the size and structure of the eggs are characteristic. 98 Other trematode eggs may occur in the feces, but only those of Paragonimus normally occur in the sputum. Specific immunodiagnosis is possible, using micro-Ouchterlony methods or immunoelectrophoretic patterns of human sera, reacted with Paragonimus antigens. 167

Epidemiology and control. Various mammals are susceptible to Paragonimus infection. Cats, dogs, mink, muskrats, and man are the usual natural hosts. Infection in lower animals is known in Asia, Africa, and North and South America, including the United States. Human infection is limited by food habits, occurring commonly only in the Far East. The metacercariae in infected crustacea are destroyed only by thorough cooking or considerable exposure to pickling sauces, and in the endemic areas

fresh-water crabs, raw or slightly pickled, are considered a delicacy. It should be emphasized that the asexual reproduction in snails is obligate and that only the metacercariae and possibly the cercariae are infective for mammals. Thus, direct transfer from mammal to mammal does not occur, and numerical increase of an individual infection is unknown in the absence of reexposure.

Chloroquine, in addition to its antimalarial activity, has been utilized with some success in a number of helminth infections inlcuding paragonimiasis. It is beneficial in early pulmonary infection but of dubious value in long-established infection or in ectopic cerebral parasitism. Good clinical results have also been reported with Bithionol. 168

Chemotherapy of human infections is useless for control, both because of its unreliability and because lower animals are an important reservoir. Destruction of snails has generally failed. The only effective control measure known is education to the dangers of eating improperly cooked freshwater crustacea. It should be noted here that while such modification of food habits is the best control method for all human trematode infections except the blood flukes,

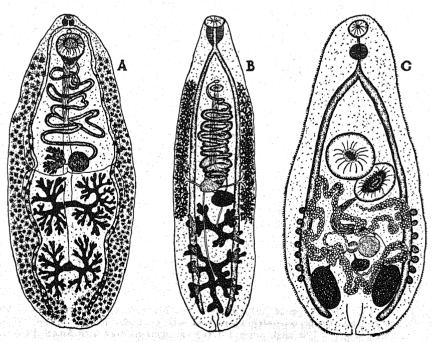

Figure 240. Trematode parasites of man. Note differences in magnification. A, Fasciolopsis buski, \times 3. B, Clonorchis sinensis, \times 5. C, Heterophyes heterophyes, \times 60.

established habits and prejudices often interpose difficulties in its execution. Yokogawa *et al.*¹⁷¹ have recently reviewed the status of knowledge of paragonimiasis.

Fasciolopsis buski. The large adults of this species attain a length of 7 cm. They are found attached to the mucosa of the small intestine of man and the pig. The infection is most common in China but occurs in other parts of Asia. The large eggs (average 140 by 80 μ) escape in the feces and develop in water, where the miracidia invade snails of the genera Segmentina and Planorbis. The development in the snail, like that of Paragonimus, comprises a sporocyst generation and two generations of rediae. The longtailed cercariae encyst as metacercariae on aquatic plants, particularly the water chestnuts. These plants, eaten raw or peeled with the teeth, convey the infection to man or the pig. Symptoms are generally related to the intensity of infection. They consist of intestinal disturbances and generalized edema. The latter has been attributed to toxemia but may be merely nutritional, resulting from the food-robbing of the host by the worms. Severe infections may cause death. As in many other intestinal worm infections, hexylresorcinol is therapeutically efficient. Control is achieved by treatment of human infections, proper sewage disposal, and education to the dangers of eating raw plants from contaminated water. The problem is complicated by the practice, common in endemic areas, of using human feces as fertilizer.

The closely related Fasciola hepatica infects the livers of sheep and cattle, causing "liver rot," and is of great economic importance. It is important also because it was the first trematode whose life cycle was described. Occasional human cases are known, usually contracted by eating fresh watercress to which metacercarial cysts are attached. Human infection is relatively frequent and clinically important in Cuba, Chile, southern France, and other scattered areas where sheep or cattle husbandry accompanies the raising of leafy vegetable crops commonly eaten uncooked. Fasciola gigantica and Fascioloides magna of herbivores also occasionally infect man. Another economically important parasite of the liver of herbivores, Dicrocoelium dendriticum, has been found rarely in man.

Heterophyes heterophyes. Heterophyes heterophyes is a small trematode, about 1.5 mm. long, of the intestine of man, cats, dogs, and other fish-eating mammals in Egypt, Asia Minor, and Asia. The eggs are small, averaging 25 by 16 μ . Metacercariae are ingested by man in insufficiently cooked or salted fish. The adult trematodes produce only minor gastrointestinal disturbances, but it is reported that the eggs are often deposited deep in the mucosa, whence they reach the general circulation and are localized in various distant tissues. The inflammation in these tissues, particularly the myocardium and brain, is said occasionally to cause serious symptoms or death.34 Several related species attack man. The most

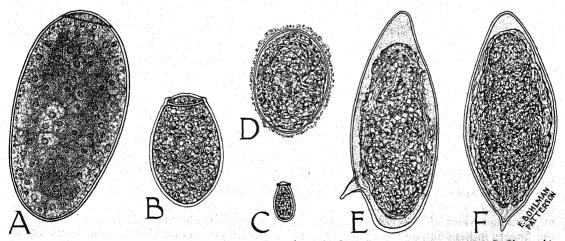

Figure 241. Trematode eggs in optical section. A, Fasciolopsis buski. B, Paragonimus westermani. C, Clonorchis sinensis. D, Schistosoma japonicum (note that the shell has the halo of debris usually seen when this egg is found). E. Schistosoma mansoni. F, Schistosoma haematobium. Camera lucida; approx. × 310.

important of these is *Metagonimus yoko-gawai*, which occurs in man and other fish-eating animals in the Balkans, Palestine, and Asia. A number of heterophyid flukes whose eggs cause extensive ectopic lesions have also been reported from man in the Philippines.²

Other intestinal trematodes. Several species of Echinostoma, Echinochasmus, and Euparyphium occasionally parasitize man. They are elongate trematodes with a ring of large spines on the head region. The human infection is acquired by ingestion of raw snails or mussels containing the metacercariae. Various mammals and birds are the normal hosts of the adult worms. Occasional human infections are also reported with Gastrodiscus hominis and Watsonius watsoni. Their life cycles are unknown, but since they chiefly parasitize herbivorous mammals it is presumed that the metacercariae are found on plants.

Clonorchis sinensis. The Chinese liver fluke, Clonorchis sinensis, is a thin, elongated trematode, 1 to 2 cm. in length. The adult worm inhabits the smaller bile ducts of man, cats, dogs, and other fish-eating mammals in China and Japan. The eggs, averaging 29 by 17 μ , pass out with the bile and escape in the feces. They are fully developed but do not hatch in the water. Upon ingestion by suitable snails, usually of the genera Parafossarulus and Bithynia, they hatch, and the miracidia become sporocysts in the lymph spaces. Rediae produced in the sporocyst give rise to long-tailed cercariae. These encyst as metacercariae in the tissues and on the skin and scales of various fresh-water fish. Metacercariae ingested by man hatch in the small intestine, and the young worms migrate up the bile ducts to develop into adults three to four weeks later. In rabbits experimentally infected, the young worms complete migration to the liver in hosts whose bile ducts have been ligated. Consequently, passage through the circulatory system to the liver or direct migration through the intestinal wall to the peritoneal cavity and into the liver surface may also occur.145 Thorough cooking (100° C. for 15 minutes) is necessary to destroy the metacercariae. Infection of man occurs by ingestion of the metacercariae, possibly in drinking water or by contamination of the fingers in handling infected fish, but usually by consumption of insufficiently pickled or cooked fish, a favorite article of diet in

the endemic regions. Hazards are increased in these areas by the practice of propagating fish for market in ponds fertilized with human feces.

Human infection is characterized by proliferation of the bile-duct epithelium and of the surrounding connective tissue. This results in liver cirrhosis, destroying liver parenchyma and obstructing portal blood flow. Intestinal disturbances, liver enlargement, and ascites are the common symptoms, severe infections resulting in death.

Although a variety of chemotherapeutic agents have been used for liver fluke infections of man, no reliable agent for the treatment of clonorchiasis has been available until recently. One of these used for the treatment of cattle and sheep liver flukes (1,4-bis-trichloromethylbenzol) has shown considerable promise, in its early trials. 169 Diagnosis depends on the identification of eggs obtained from feces or by duodenal intubation. There have been a number of efforts to develop practical immunodiagnostic methods for clonorchiasis. However, most of these cross-react with other trematode infections, such as paragonimiasis and schistosomiasis. A purified antigen prepared from adult clonorchis and consisting primarily of a polyglucose has been shown to have high specificity when used in a complement fixation test in this infection. 134 Control, as in the trematode infections discussed above, depends principally on education concerning avoidance of undercooked infected food, in this case fresh-water fish.

A closely related species, Opisthorchis viverrini, is of considerable importance in northern Thailand, where it infects 25 per cent of the population. 129 Opisthorchis felineus and O. tenuicollis infect fish-eating mammals and, less commonly, man in parts of Central Europe and Asia.

Human blood flukes: the schistosomes. The high incidence of infection of man with the several species of schistosomes, as well as the chronic debilitating disease produced, places these organisms among the world's most important infectious agents. The world incidence of infection is estimated to be greater than 4 per cent and some areas of endemicity are increasing in size. Ontrol measures and treatment of the individual are still inadequate. Bilharz, in 1852, first described trematodes in the veins of an Egyptian, and subsequently infection with the schistosomes was termed "bilharziasis"

in much of the medical literature. The worms are usually found in pairs in the portal venous system or in veins of the vesicle plexus with the female held in the ventrally grooved male gynecophoral canal. The split body of the male suggests the generic name for the group and, unlike the other trematodes mentioned, all blood flukes are dioecious. The adults attach to the walls of the blood vessels with their suckers and migrate to the smaller venules in copula for egg deposition. Occasionally they may develop in ectopic sites, probably being carried there by the circulation prior to attaining maturity. The blood flukes rely on a supply of carbohydrate and utilize glucose from the blood. 17, 160 In addition they ingest erythrocytes and have a globin-splitting enzyme. 149 Schistosoma mansoni is used here as an example of the group.

Morphology and life cycle. The paired adults of S. mansoni are normally found in the smaller mesenteric veins. The cylindrical female is 1 to 1.5 cm. in length by about 0.25 mm. in diameter. An anterior sucker surrounds the mouth and shortly behind it is a stalked acetabulum. The intestinal ceca unite before the middle of the body to form a single tube continuing to the posterior end. An oval ovary lies immediately anterior to the union of the intestinal ceca, and the uterus, containing eggs, extends forward to

open behind the acetabulum. The posterior half of the body is occupied by vitellaria. The male is shorter than the female, about 1 cm. long by about 1 mm. in diameter, its integument covered with coarse tubercles. The suckers and alimentary tract are similar to those of the female. The reproductive system consists of a cluster of eight or nine round testes in the anterior region emptying into a seminal vesicle, which opens to the outside just behind the ventral sucker.

S. mansoni has large eggs, averaging 150 by 65 μ , with no operculum but with a prominent spine at the side. They are deposited in the fine venules of the mesenteric veins in the wall of the intestine, where they lodge after the retreat of the ovipositing worms and the collapse of the vessels which had been distended by the worm body. The lateral spine aids in fixing the egg in the vessel and by a combination of events, probably including secretion of lytic substances by the developing embryo, the egg passes through the vessel wall. From the tissues the eggs continue migration through the mucosa and into the lumen of the intestine. They are mature at the time they leave the body in the feces. On dilution of the feces with water, the shell ruptures, releasing the miracidium. In suitable snails, Biomphalaria in Africa and Australorbis glabratus in the Western

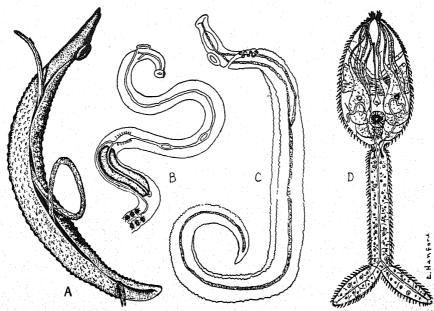

Figure 242. Schistosoma mansoni. Note differences in magnification. A, adult worms, \times 8. B, anterior end of female worm, \times 20. C, adult male, \times 10. D, cercaria, \times 180. (A and C redrawn from Manson-Bahr. D. redrawn from Cort.)

Hemisphere, the miracidium penetrates and two generations of sporocysts are produced resulting, after about six weeks, in the production of cercariae with long, forked tails. Escaping into the water the cercariae swim actively or rest at the surface, dying in about three days if they do not reach a susceptible final host. Coming in contact with human skin they attach and actively penetrate the skin. The epidermis is passed quickly and the cercariae shed their tails and may reach lymph vessels in the dermis within 15 minutes or less. This rapid invasion of the unbroken host skin is accomplished through use of cercarial enzymes as well as by muscular activity. A major feature of cercarial morphology is the possession of sets of large unicellular "penetration glands" which are the source of mucoid secretions, collagenaselike proteases, and mucopolysaccharidases, all presumed to be of importance in invasiveness of these parasites. 92, 141 The parasite is carried via lymph and blood to the portal veins in the liver, where maturation occurs and the adult forms mate and migrate distally in the portal system to the mesenteric veins. Four to eight weeks after infection the sexually mature worms begin egg production. The infection may persist for over 25 years without re-exposure.

The other species of human blood flukes differ from S. mansoni in size, details of morphology, egg structure, location in the definitive hosts, types of snail hosts, and geographical distribution. S. haematobium adults occur predominantly in the venules of the urinary bladder wall, the eggs escaping in the urine. The eggs are large, 150 by 60 μ , with a terminal spine. The male, 1 to 1.5 cm. long, is covered with fine tuberculations and has four large testes. The female is about 2 cm. long. Snails of the genera Physopsis and Bulinus serve as intermediate hosts.

S. japonicum occurs in the venules of the intestine. The eggs average 80 by 65 μ , with a small lateral knob rather than a spine. They escape in the feces, the miracidium invading snails of the genus Onocomelania. The male is 1 to 2 cm. long, with a smooth integument, and has seven or eight testes. The female is 1 to 2.5 cm. long.

Schistosomiasis. The disease produced by the schistosomes varies with the infecting species, the number of adult worms present, and with the duration of infection. The pathology may conveniently be divided into the incubation period, from skin penetration to egg deposition, the acute stage, and the chronic stage. At the inception of the incubation period, skin penetration may cause a mild transient dermatitis. In the forms normally parasitizing man this is less severe than that produced in man by the penetration of cercariae normally parasitizing other vertebrates (see below). The larvae in passing through the lung may cause an eosinophilic infiltration and while developing in the portal system, parasite metabolic products cause a toxic hepatitis often accompanied by irregularly fluctuating fever and allergic manifestation such as urticaria. This is followed by the acute stage in which eggs are actively deposited in the tissues and are extruded into the lumina of the intestine or bladder. During this period trauma may produce intestinal hemorrhage and pseudodysentery in S. mansoni and S. japonicum infections. Hematuria is characteristic of this stage of S. haematobium infections. 56, 114 Even in these early stages numerous eggs may escape into the circulation rather than migrating through tissues to organ lumina. These embolic eggs lodge in numbers in the liver, where they become enclosed in small granulomata (pseudotubercles) and in S. haematobium and S. *japonicum*, numbers commonly pass to the lung. In many instances in S. japonicum, relatively large numbers reach the brain, producing the symptomatology of cerebral damage. The chronic stage is due to the host's reaction to continuous egg-produced tissue damage. In S. mansoni the wall of the large intestine becomes thickened with scar tissue and rectal polyps of connective tissue with eggs may be extensive. Similarly, impairment of the small intestine and thickening occur with S. japonicum, and in both, cirrhosis of the liver is a most important sequel. With S. haematobium the wall of the urinary bladder is greatly thickened with fibrous connective tissue and the urethral lumen is commonly reduced. 69 The external genitalia are also commonly involved. Carcinomas of the rectum, liver, and urinary bladder are often observed and in some areas a high correlation between these malignancies and schistosomiasis is claimed.

Concomitant with the liver damage found in S. mansoni and S. japonicum infections, circulatory impairment produces portal hypertension, splenic enlargement, esophageal varices, and ascites.^{5, 52} As briefly summarized above, the pathology produced varies with time and also with the differing site of

egg deposition by the different species of adult worm. Another important species difference in the disease is the fact that the female S. japonicum produces 10 times the number of eggs per day as the S. mansoni female. Egg production of the female S. haematobium is believed to be intermediate between these.

IMMUNITY. Direct evidence of functional immunity to schistosomes in man is lacking. Children and young adults commonly have severe infections which may terminate fatally. Some infected adults are found without symptoms of progressive disease under conditions where it may be assumed that they have periodic exposure to reinfection with S. japonicum or S. mansoni. Animals cured of initial infection show some resistance to reinfection and, in monkeys, some individuals surviving initial infection are strongly immune to massive reinfection. 158 Recent evidence indicates promise that immunization by vaccination may be possible as rhesus monkeys inoculated with a nonhuman (Formosan) strain of S. japonicum exhibited considerable resistance to challenge with the human strain (Japanese).⁷³ In addition, mice inoculated with cercariae of S. mansoni that had been exposed to 60 cobalt radiation developed a relative immunity to reinfection with nonirradiated cercariae. 156

A wide variety of serological evidence of antibody production in schistosome infection exists and in individual human sera circumoval precipitins, miracidial agglutinins, cercarial agglutinins, complement-fixing, and other antibodies can be demonstrated.⁸² In addition, serum proteins inhibiting cercarial penetration enzymes are also produced.⁹² To date these serological phenomena cannot be correlated with the degree of functional or protective immunity of the individual.

DIAGNOSIS. Laboratory diagnosis is based on the finding of characteristic eggs in the feces, urine, rectal biopsy, or rarely, liver biopsy. In very early or in late chronic stages the eggs may not readily be found, and multiple examinations plus concentration techniques must be routine for diagnosis of individual infections. Immunological techniques are also valuable both for the individual diagnosis and for epidemiological surveys. These include the production of precipitate about viable or lyophilized eggs (circumoval precipitin reaction), high titer hemagglutination of erythrocytes sensitized with adult antigens, intradermal reaction to adult antigens, binding of fluorescent antibody by preserved cercariae, ¹³¹ and a variety of other methods including complementfixation and gel precipitation techniques.⁷⁴ Some of the reactions are group-specific, persist after cure, or are negative in a high percentage of the lower age group. The circumoval, fluorescent antibody, and intradermal tests are of practical value if their limitations are understood.

THERAPY. The most effective treatment of all three species is the intravenous administration of potassium or sodium antimony tartrate, which properly administered will provide a high percentage of cures (84 per cent in S. japonicum). 16, 18 This tartar emetic requires slow administration on alternate days over a one-month period, is painful, and not practical for mass treatment. Consequently Fuadin (Stibophen), an intramuscularly administered antimonial, is a favored drug in many of the endemic areas. Characteristically, it sterilizes temporarily the female schistosome, causing cessation of egg-laying and of symptoms referable to this damage. Properly used, cures may be effected. However, the cure rate is low, since a proper course of therapy is seldom followed and the female worms are believed to recover. The mechanism of action of the trivalent antimonials is an interference with one of the enzymes (phosphofructokinase) of the helminth carbohydrate metabolism.¹⁷ Miracil D, an orally administered drug, has been shown to be of some value in the treatment of S. haematobium infections and is of particular value in small children.

Epidemiology and control. The chief means of infection is by contact of the skin with water containing the cercariae. This occurs especially in the working of rice fields fertilized with human feces, but also in bathing and chance contact. Infection may be acquired from drinking water and rarely as an intra-uterine infection. Man is the only important reservoir of S. mansoni and S. haematobium infection although both occur naturally in monkeys and rodent infections of S. mansoni have been described. The disease is for these two species perpetuated by the promiscuous discharge of urine and feces by man or their deliberate use as fertilizer in the cultivation of rice, sugar cane, and similar crops. Infection of streams and irrigation canals used for ablution and the washing of clothes is important in maintenance of the infection. In contrast to these forms, S.

addenie int

japonicum has numerous reservoir hosts among domestic and wild mammals which pass eggs in feces and may maintain the infection in man's absence. S. mansoni is widely distributed throughout Africa whereever suitable snail intermediate hosts are found. The delta of the Nile is an endemic area of primary importance; it is common throughout tropical Africa to South Africa and in much of its range coexists with S. haematobium. Importation of S. mansoni with slaves established the disease in Brazil, Venezuela, Surinam, and the West Indies including Puerto Rico. In these areas it remains of major importance and the world incidence approaches 40 million. The present distribution of S. haematobium not only includes all of Africa suitable for its development but also parts of Arabia, Palestine, Lebanon, Syria, small endemic areas in Portugal, and India. S. japonicum is limited to the Far East with important endemic areas, in the Philippines, China, the Celebes, and Japan. A number of small foci have been found in Thailand and Laos, and a strain primarily parasitizing dogs and rats is found in Taiwan.

Control of schistosomiasis depends on destruction of the snail intermediate hosts, prevention of access of eggs to water containing snails, or avoiding contact with cercaria-containing waters. Some limited success has been obtained in snail control using copper sulphate or sodium pentachlorophenate as molluscicides. 101 Periodic drying of irrigation ditches is of some value for the control of snails transmitting S. mansoni and S. haematobium but of little value in S. japonicum control as the snail host is operculate and resists desiccation. As it does not survive well in ponds or in welldrained areas, ponding and drainage are utilized in control. In limited areas having special characteristics the introduction of a competitor, the snail Marisa, has eliminated Australorbis, the host of S. mansoni. 119 Safe sewage disposal and increased sanitation has not met with outstanding success as a control measure, since the customs of the people as well as the economics of the endemic areas operate against these methods. Avoidance of contact with infected water is difficult in some areas, since it is also associated with religious habits of ablution; in other areas only infected waters are available for drinking and general cleansing, and it has not been economically possible to provide safe water supplies.

Other schistosome species. A number of species commonly parasitizing ungulates of Africa and India, including S. bovis and S. spindale, have been reported as occurring in man. Several hundred cases of S. intercalatum in man have been reported from tropical Africa. This form has a terminal-spined egg slightly larger than that of S. haematobium. The eggs are passed in the feces rather than in the urine.

Schistosome dermatitis. Several species of schistosomes, especially in the genus Trichobilharzia, may invade the skin of man to cause severe allergic dermatitis. These worms, which normally parasitize birds or lower mammals, apparently cannot mature in man. While dermatitis-producing schistosomes have been recorded from scattered areas throughout the world, excepting Africa, they are prominent only in parts of Europe and North America. Certain lakes in the north central states, particularly in Michigan and Wisconsin, were formerly notorious for the "swimmer's itch" contracted by bathers.31 Although snail destruction with copper salts has successfully controlled the infection in some of these areas, this type of cercarial dermatitis continues to be a serious problem over much of this area. The dermatitis can be treated with anti-allergic ointments. One of the parasites producing schistosome dermatitis, Schistosomatium douthitti, is of especial interest because it is easily studied in laboratory mice. Recently, avian schistosomes causing a marine dermatitis have been described from salt-water beaches of Hawaii, California, and the eastern United States.²⁶

CESTODA

The cestoda, or tapeworms, generally consist of a colony-like chain of flattened segments, each of which is a semi-independent unit with a complete set of reproductive organs. A scolex at the anterior end of the chain serves to anchor the worm in place, and the nervous and excretory systems are shared by the whole organism. There is no alimentary tract, soluble food substances being absorbed through the body surface. All tapeworms are parasitic, the adults usually in the alimentary tract of the definitive host and the larval stages in the tissues of an intermediate host.162 Two orders of tapeworms, the Pseudophyllidea and Cyclophyllidea, contain human parasites. The Pseudophyllidea are discussed later (see

Diphyllobothrium latum). Most of the tapeworms of man belong to the Cyclophyllidea, of which Taenia solium will serve as an example.

Taenia solium. The pork tapeworm, Taenia solium, was known in ancient times. Küchenmeister, in 1855, first suspected its relationship to "bladderworms" in pork and demonstrated their transformation into the adult worms in the intestine of a condemned criminal.

Characteristics and life cycle. In the intestine of man the adult T. solium attains a length of 2 to 3 meters. Buried in the intestinal mucosa of the host is the scolex, or "head," a rounded cubical organ about 1 mm. in diameter bearing four large, cup-like suckers and a pad, the rostellum, with 20 to 35 hooks. Behind the scolex is a thin neck which merges into a region of proliferation of segments, or proglottids. As new segments are produced, the older ones are pushed back, developing sexually, until near the middle of the worm mature proglottids are found. They average 0.5 cm. square. The genital pore occurs on either side of the proglottid, alternating irregularly from segment to segment. The male reproductive system consists of small follicular testes scattered throughout the dorsal part of the segment, emptying through vasa efferentia into a coiled vas deferens which ends in the muscular copulatory organ, or cirrus, at the genital pore. In the female system the vagina extends from the genital pore to the oötype in the posterior central part of the segment. On either side of the ootype are ovaries and behind it the vitellaria. A blind uterus extends forward from the ootype.

As the segments move toward the posterior end of the worm, the uterus fills with eggs, becoming branched to fill most of the segment in the gravid proglottid, which is about 0.5 by 1 cm. in size. In T. solium there are about 10 branches on each side of the uterus. The gravid segments become detached singly or in small groups and pass out with the feces. Before or after escape from the body they disrupt, releasing large numbers of eggs. These eggs, averaging 35 μ in diameter, are nearly spherical and provided with a thick "shell" of characteristic porous structure. Within the shell is seen the onchosphere, an embryo bearing six hooks.

Ingested by a suitable intermediate host, the eggs hatch in the intestine and the embryos penetrate the intestinal wall to enter the blood or lymph. They are carried to various parts of the body, developing in the tissues in about two months to the infective stage. Infection is most intense in the muscles, but other tissues also contain the parasites. This stage, a cysticercus, consists of a scolex like that of the adult, a short neck, and a fluid-filled sac about 1 cm. in diameter. Because of the sac, this larval stage is commonly called a "bladderworm." In the tissues the scolex is invaginated into the bladder. In addition to the pig, other animals may harbor the cysticerci. Among them is man, in whom they occur in various tissues including the brain.

Man acquires the adult tapeworm by ingestion of undercooked pork containing the cysticerci. In the intestine the bladder is digested away, the scolex attaches to the intestinal wall, and the adult worm develops

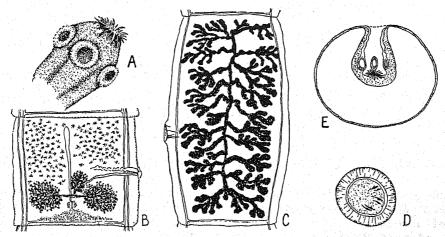

Figure 243. Taenia solium. A, scolex, \times 20. B, mature proglottid, \times 5. C, gravid proglottid, \times 5. D, egg, \times 500. E. cysticercus, \times 5. (Adapted from various sources.)

by growth from the neck region. By two months after infection gravid proglottids containing eggs are being passed in the feces. Infection may last for many years.

The human disease. Adult pork tapeworms usually occur singly in the intestine of man. They often cause no noticeable symptoms, though general intestinal discomfort may occur, and in children nervous disturbances are sometimes seen. The ravenous appetite popularly associated with tapeworm infections is actually uncommon, loss of appetite being more frequently observed. In contrast with infection by the adult worm, tissue infection with the cysticerci is dangerous. The larvae act like benign tumors; growth is slow and terminates naturally with full development. The injury results from pressure, and its seriousness, therefore, depends on the location of the larvae. In most muscles and connective tissues they are of no consequence, but larvae in the eye may affect vision. In the brain they may give rise to epilepsy or other manifestations of local pressure.

There is no evidence of acquired *immunity* to *T. solium* in man, though it has been suggested that the rarity of multiple infections in the intestine indicates immunity to superinfection. In individuals harboring the cysticerci, complement-fixing and precipitating antibodies are detectable. They react with extracts of other tapeworms as well as *T. solium*.

Laboratory diagnosis of intestinal infection with T. solium is based on recovery of eggs or gravid proglottids from the feces. The eggs are not distinguishable from those of the beef tapeworm (see below), but the gravid segments can be identified by the smaller number of uterine branches, about 10 on each side as against more than 15 in the beef tapeworm. Diagnosis of the cysticercus infection is rarely made before operation or necropsy, but the immunological reactions mentioned above have been used. Quinacrine hydrochloride (Atabrine) is used in treatment by tablet or sometimes by duodenal intubation. Extract of male fern (Oleoresin of Aspidium), an old therapeutic agent, is still used in some instances. There is no treatment known for the larval infection except surgery.

Epidemiology and control. The larvae of T. solium occur most commonly in pigs but are found also in man, monkeys, sheep, camels, and dogs. Before 1850 in Berlin 2 per cent of human autopsies showed the cysticerci, but the incidence is now much lower. Pigs acquire the infection by contamination of their food or water with human feces. In some areas of the tropics and the Far East pigs, because of their coprophagic habits, are responsible for the relative cleanliness around small rural villages. Larval infections in man are incurred chiefly by contamination of food, water, or fingers with eggs from human feces, but it is also possible that in the intestine of an individual harboring the adult worm the eggs may hatch without reaching the outside. Whether or not eggs must leave the body before they are infective, a person with the adult worm in his intestine is a constant hazard to himself as well as to others. Man, the only known host for the adult tapeworm, acquires the infection by ingestion of undercooked pork, which often contains large numbers of larvae. Freezing and thorough cooking kill the larvae, but ordinary pickling and smoking are ineffective. Government meat inspection reveals most infected carcasses and has been the most effective single control measure. Other control methods are directed at the prevention of contact between pigs and human feces.

The beef tapeworm, Taenia saginata. Taenia saginata, resembles T. solium in morphology and life cycle, but several differences are noteworthy. The scolex is "unarmed," lacking the hooked rostellum of T. solium. The adult worm is usually about 5 meters long, but occasionally is much longer. The gravid proglottids are distinguished from those of T. solium by a larger number of uterine branches, usually 15 to 20 on each side. Man is the only known host of the adult. The cysticerci develop in cattle and other ruminants, human infection resulting chiefly from consumption of undercooked beef. Rare cases of human infection with the larvae have been claimed, but it is probable that they were abnormal cysticerci of T. solium.

Echinococcus granulosus. The adult of Echinococcus granulosus inhabits the intestines of dogs and related species. It is a minute worm 0.25 to 0.5 cm. in length, consisting of an "armed" scolex and three proglottids, one immature, one mature, and one gravid. Large numbers of the adults may occur in the intestine of an infected dog.

The natural intermediate hosts are sheep, cattle, and other ruminants, but a wide va-

riety of animals are susceptible, including man, in whom the larva causes a serious disease. This larva is markedly different from those of the beef and pork tapeworms discussed above. In the viscera of an infected animal it attains a diameter of about 1 cm. after five to six months. It is infective after eight months or more but continues to grow, often, after several years, reaching a diameter of more than 20 cm. The larva, known as a "hydatid cyst," is a spherical, fluid-filled sac composed of a thick cuticular wall with a thin germinative epithelium on its inside surface. From this germinative epithelium are formed two types of structures. Buds may appear and grow into stalked vesicles, brood capsules, on the inner surface of which stalked cysticercus-like "scolices" are produced. These brood capsules may become detached as daughter cysts, enlarge, and produce brood capsules and scolices within themselves. In the large cysts there may thus be produced many thousand infective scolices, each of which can develop into an adult worm if the cyst is eaten by a dog feeding on the viscera of an infected animal. Thus E. granulosus differs from T. solium chiefly in the fact that multiplication occurs in the larval as well as the adult stage. The predominant site of larval infection is in the liver. The lung is next in importance, and cysts may occur also in practically every other organ.

Hydatid disease in man. Echinococcosis, or hydatid disease, is characterized by two general types of manifestations. First, hypersensitivity develops to components of the hydatid fluid, and accidental rupture of a cyst may cause serious, even fatal, reactions. Second, and most important, the growing cyst acts like a tumor, the injury resulting from pressure effects and depending on the localization of the cyst. Rupture of a cyst may give rise to new cysts produced from scolices, daughter cysts, or fragments of germinative epithelium. Osseous cysts, occurring in bone, may weaken the bone by erosion of its structure.

There is no information available concerning acquired *immunity* to the larval infection in man, though in immunized sheep the cysts develop somewhat abnormally. Dogs injected with antigens derived from the larvae are immune to infection with the adult worm.

Laboratory diagnosis is usually based on immunological reactions. The precipitin test

and the Casoni intradermal reaction are both useful but remain positive after removal of the cysts. The most reliable test is the complement-fixation reaction, utilizing merthiolate-preserved cyst fluid as an antigen.

Epidemiology and control. The normal life cycle of E. granulosus involves dogs and sheep or cattle, man being an accidental host of the larva. For this reason, the infection is most common in the great grazing regions of the world, particularly Australia and New Zealand, North and South Africa, Iceland, and southern South America. The incidence in cattle and sheep occasionally exceeds 50 per cent. Various wild mammals may also be involved, among them moose, reindeer, and wolves in northern North America. Transmission of Echinococcus eggs to food by sarcophagic flies from dog feces has been experimentally demonstrated and may be presumed to occur naturally.

Control of the infection in domestic animals depends chiefly on preventing dogs from eating offal. Possibly infected waste material should be buried or burned. Prophylaxis of human infection requires measures to reduce the chance of contamination of human food and water by feces of dogs.

Echinococcus multilocularis. The adult of *E. multilocularis* differs from *E. granulosus* only in fine morphological detail. The larva, however, develops differently from the discrete, spherical cyst produced by the latter, forming an *alveolar cyst* which spreads malignantly as a foaming mass of minute, budding globules, each containing, in the normal hosts, a few scolices. The liver is usually infected, and it is extensively destroyed by the exuberant growth of the larval tissue. ¹⁵⁷

E. multilocularis has been found in central Europe and the Aleutian Islands but probably also occurs in northern Asia. The adult hosts are foxes, and the larvae normally parasitize wild rodents. Sporadic larval infections occur in man, causing usually fatal destruction of liver tissue.

Alveolar hydatid was known in man for nearly a century before, in 1951, Rausch and Schiller recognized it as a distinct species. It had previously been considered an abnormal form of *E. granulosus*. The name *E. alveolaris* has also been applied to it.

Hymenolepis nana. The human dwarf tapeworm, Hymenolepis nana, is a small worm, 1 to 4 cm. in length, with mature proglottids 0.5 to 1 mm. in breadth. The scolex is similar to that of T. solium but smaller,

about 0.25 mm. in diameter. The mature proglottids are markedly different in appearance from those of *T. solium*, the width being more than four times the length. Three large testes occur in each segment. The uterus in the gravid segments is a large, irregular sac. The gravid segments are usually destroyed in the intestine, releasing the eggs, which are found in the feces.

H. nana is unique among human tapeworms in not requiring an intermediate host. Ingested eggs hatch in the intestine of man to release an embryo which invades the tissues of an intestinal villus. Here, in about four days, it develops into a cysticercoid, a larva with a small bladder and a solid tail. This larva breaks out of the intestinal wall. attaches to the mucosa, and develops into the adult worm. Eggs are found in the feces about two weeks after infection. It is reported that several types of insects can serve as intermediate hosts, but they are probably unimportant in human spread of the parasite. Large numbers of worms are commonly found in an infected individual, and they may give rise to intestinal and nervous disturbances in children. Epileptiform convulsions may occur. Ouinacrine hydrochloride (Atabrine) and extract of male fern are useful drugs for elimination of the worms.

H. nana occurs naturally in man, monkeys, and rodents. Although the form in rodents has been separated as a distinct species, H. fraterna, it is generally considered a variety of H. nana. The parasite is cosmopolitan. It is much the most common tapeworm of man in the United States, especially prevalent in children, but occurring in all age groups. Age resistance has not been shown in man but is experimentally demonstrable in rats and mice.

The lack of an intermediate host permits direct spread from man to man. It is not known whether the eggs can hatch without having reached the outside. However, an infected individual is particularly liable to reinfection from fingers contaminated with his own feces.

The closely related *H. diminuta* of rats and mice is transmitted by several species of insect intermediate hosts. Occasional human infections have been reported, mostly in children.

Tapeworms of lower animals. Species of the genus Multiceps exhibit the adult stage in dogs and larval stages in sheep. The larva, known as a *coenurus*, resembles a cysti-

cercus but has a number of scolices attached to a single bladder. In the brains of sheep the larvae produce a fatal disease. Occasional cases have been reported in man.

Taenia pisiformis is a common tapeworm of dogs and cats, the larvae developing in the abdominal cavity of rabbits. T. taeniaeformis occurs commonly in the intestine of cats. The larvae, strobilocerci, normally develop in the liver of rats or mice. There is considerable evidence that in the rat the larvae produce malignant tumors. These have also been produced by larval extracts in the absence of the living parasite and once developed are metastasizing and transplantable.³⁶ This species is of interest for a number of immunological phenomena. Definite sex resistance is shown by the fact that female rats acquire fewer larvae from a given dose of eggs than do males. Castration of females or injection of male sex hormones reduces their natural resistance, while female hormones increase the resistance of the males.²³ Acquired immunity is dependent in part on antibodies transferable with serum. Two antibodies are detectable. One acting early in the infection prevents development of the larvae; it is elicited by both infection and vaccination and is removed from the serum by absorption with worm substance. The other acts late in the infection, aborting the development of the larvae in the liver; it is elicited by infection but not by artificial immunization and is not absorbable with parasite material.

Dipylidium caninum, a common parasite of the intestines of dogs and cats, measures 10 to 50 cm. in length. Each elongate, rounded mature proglottid contains two sets of reproductive systems, one opening on each side of the segment. The uterus breaks up into pouches, each containing several eggs. Dog lice and various species of fleas serve as intermediate hosts, the cysticercoids in the insects being infective when ingested. Young children occasionally harbor the adult tapeworm. 106

Diphyllobothrium latum. The fish tapeworm Diphyllobothrium latum (or Dibothriocephalus latus) is the most important human parasite in the order Pseudophyllidea. It differs markedly in structure and life cycle from the species discussed above. It is a more primitive type, in many respects showing strong resemblances to the trematodes.

Morphology and life cycle. The adult worm in the intestine of man is very large,

often exceeding 10 meters in length. The scolex is an elongate ovoid structure, about 1 by 2.5 mm. in dimensions, bearing, instead of the circular suckers of the cyclophyllidea, two elongated grooves which serve as attachment organs. The mature proglottid is broader than long, about 4 by 10 mm. in size. The small testes are scattered throughout the lateral dorsal regions, emptying by fine ducts into the vas deferens. This coiled tube runs from the posterior center of the segment forward to the muscular cirrus. which opens into the ventral genital pore in the middle of the anterior region. The vagina extends from the genital pore back to the large oötype in the center of the posterior region. The ovaries lie on either side of the ootype, and the vitellaria are small follicles scattered throughout the lateral ventral regions. Arising from the oötype, the eggfilled uterus coils throughout the center of the proglottid, ending at the uterine pore just behind the genital pore. This permits escape of the eggs without rupture of the proglottid, so that, contrary to the usual situation as seen in T. solium, the eggs are released into the intestinal contents and escape in the feces. The spent proglottids at the end of the worm break off and are passed in the feces.

The egg is undeveloped when it escapes in the feces, embryonation requiring a week or more in water. Like the eggs of most trematodes it is ovoid, with an operculum. Average measurements are 65 by 45 μ . Hatching occurs by opening of the operculum to release a free-swimming, spherical, onchosphere covered with long cilia. This embryo, the *coracidium*, dies within a few days un-

less it is ingested by a suitable small crustacean, one of several species of copepods of the genera Cyclops and Diaptomus. Losing its cilia, the embryo reaches the body cavity of the copepod and becomes, in two to three weeks, an elongated solid body with a round tail bearing the six hooks seen in the embryo. This stage, the *procercoid*, is about 0.5 mm. long.

If the infected copepod is eaten by a fish, the procercoid penetrates the wall of the intestine and reaches the viscera or muscles. Here, in a week or more, it transforms into the *sparganum*, a worm-like stage 0.5 to 2 cm. long with a rudimentary scolex at the anterior end. This stage, ingested by man in undercooked fish, develops to the adult worm in the intestine, and eggs may be found in the feces after three weeks or more. If the infected fish is eaten by another fish, the spargana become established in the tissues of the second fish and remain infective for man. Human infections have been known to persist for years.

The human disease. D. latum commonly produces multiple infections, a number of worms occurring in the same intestine. The adult worms usually cause no symptoms, though in heavy infections intestinal disturbances may occur, sometimes with generalized edema. A small proportion of infected individuals show severe anemia, indistinguishable from pernicious anemia. It has been shown that the tapeworm concentrates vitamin B₁₂ in its tissues, and it is clear that the consequent deprivation of a susceptible individual precipitates the anemia. Satisfactory data on acquired immunity are not available. Laboratory

diagnosis depends on identification of the eggs in fecal smears. As with the other tapeworms, quinacrine hydrochloride is the drug of choice.

Epidemiology and control. The adult worm parasitizes man, cats, dogs, bears, and other fish-eating mammals, but man is probably the principal source of infection in endemic areas. Susceptible copepods are widespread, and a variety of fishes can serve as second intermediate hosts. Endemic centers are known in northern and central Europe, northern Asia, Japan, parts of Africa, and the Great Lakes region of North America. Infection is especially widespread in Finland, where the incidence has been estimated at 20 to 25 per cent and where most of the cases of tapeworm anemia have been reported. Personal protection depends on thorough cooking or freezing of fish from endemic areas and care in handling of such fish. Other control methods are aimed at reducing the pollution of bodies of water with untreated human feces and at the supervision of transportation of possibly infected fish.

Related species. Several related species of tapeworms, normally parasites of lower animals, are reported occasionally in man. Man also occasionally harbors the spargana of several species of Diphyllobothrium, normally parasites of the dog and other carnivores. D. mansoni is a common example. 107 Infection with these larvae in the subcutaneous tissues, muscles, or eye is

known as sparganosis. Among the larvae infecting man is the very rare parasite, Sparganum proliferum, which multiplies enormously in the subcutaneous tissues and may cause death. The adult of this species is unknown. Larval infections with Diphyllobothrium usually result from ingestion of copepods in drinking water. In parts of the Orient split frogs are sometimes used as poultices, and human sparganosis has resulted from the migration of spargana from the frog tissues into the exposed tissues of man.

NEMATODA

All the important human parasites in the phylum Nemathelminthes (Aschelminthes of some authors) belong to the class Nematoda. They are cylindrical, elongated worms, unsegmented and with a body cavity which is not lined with a peritoneum of mesodermal origin as in higher animals. Symmetry is primitively bilateral. Male and female reproductive systems usually occur in separate individuals noticeably different in general appearance.25, 133 In some parasitic forms, parthenogenesis and protandry occur. Free-living nematodes are among the most numerous of animals and are found in a tremendous variety of habitat. Parasitic species in plants and animals are also abundant, and wild vertebrates are usually parasitized as are many invertebrates. Nematodes

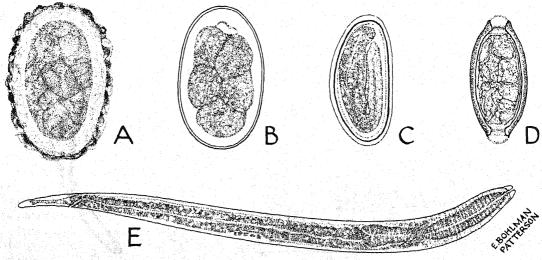

Figure 245. Nematode eggs and larvae. A, Ascaris lumbricoides. B, Necator americanus. C, Enterobius vermicularis. D, Trichuris trichiura. E, Strongyloides stercoralis (rhabditiform larva). × 400.

are important as disease agents of most domestic animals and the majority of mankind is infected with one or more species.

The structure of the nematodes parasitizing man varies greatly, and in size alone species occur which are too small to be readily seen with the unaided eye as well as forms over one meter in length. The life cycles are also varied from simple direct forms of development to those requiring several hosts. Among the simple forms, the pinworm of man, *Enterobius vermicularis*, will serve to illustrate the morphology and life history.

A word of caution is necessary here. The order of presentation of species in this section, based primarily on life cycles, cuts sharply across the lines of zoological classification, separating closely related types and bringing together types of very different structure.

Enterobius vermicularis. The human pinworm, Enterobius vermicularis, normally inhabits the upper large intestine of man, occasionally invading the female genitourinary system. The female worm, about 1 cm. long by 0.5 mm. in diameter, is a spindleshaped organism with a long, pointed tail (see figure). The outer covering is a smooth, impervious, flexible cuticle, characteristic of nematodes in general. This cuticle, together with the fact that the body musculature is exclusively longitudinal, gives the worms a characteristic bending, wriggling type of movement. Among nematodes the cuticle shows great variety of external structures - knobs, fins, papillae, etc. - which are of value in technical identification of species. The alimentary tract consists of a mouth at the anterior end, a muscular esophagus with a posterior bulbous enlargement, and a thin-walled intestine emptying through the anus near the posterior end. The female reproductive system empties through a short vagina a little in front of the middle of the body. Extending forward and back from the vagina are two separate eggproducing systems (one to several in other nematodes). Each consists of a broad uterus filled with eggs, followed by a short narrow oviduct, which terminates in a long, thin ovary coiled about in the body cavity.

The male worm is smaller than the female, 2 to 5 mm. in length and 0.1 to 0.2 mm. in diameter, the posterior end coiled into a tight spiral and lacking the pin-like tail of the female. The male reproductive system is a single tube consisting of a testis, a vas deferens, a seminal vesicle, and a muscular ejaculatory duct, provided with glands, which empties with the intestine into a cloaca. A sharp copulatory spicule can be extruded through the anus. The posterior end has minute expansions (more prominent in many other nematodes) which form a clasping bursa used in copulation.

Some of the eggs escape in the intestine, passing out in the feces, but usually the gravid females migrate out of the anus to release their eggs on the surrounding skin. The eggs average 55 by 25 μ in size, usually show mature embryos when passed, and are infective within a few hours. Ingested by man they hatch in the small intestine, where the worms mature and mate before passing down to the large intestine. Eggs appear in the feces about two weeks after infection. The adults in the intestine are short-lived, but infection is maintained or increased in the individual by self-infection. Hatching of eggs on the perianal surfaces with subsequent migration of larvae into the anus (described as "retroinfection") occurs in related species and it has been suggested this may also occur in man.

Pinworm infection in man. The adult worms in the intestine have little or no effect on the host. However, they occur in the

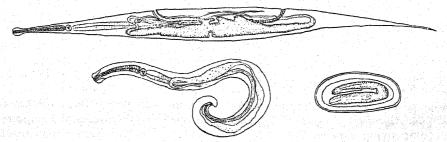

Figure 246. Enterobius vermicularis. Top, female, × 15. Left, adult male, × 15. Right, egg, × 300. (Redrawn from Faust after Leuckart.)

vermiform appendix, and since they are said to be more common in diseased than in normal appendices, they have been suspected of an etiological role in appendicitis. During the nocturnal emergence of the female and with egg deposition in the perianal region, itching occurs which may be intense, leading to scratching, scarification, weeping eczema, and bacterial infection. Worms may enter the female genitalia and cause similar irritation and occasionally migrate into the peritoneal cavity via the fallopian tubes. In children pruritus ani, sleeplessness, and resulting irritability are common. A slight eosinophilia may accompany infection and no immunity is known to develop.

Diagnosis is based on identification of eggs in the feces or from the perianal skin. The best method utilizes a strip of cellophane tape. The gummed side is pressed repeatedly on the perianal skin and then applied to a microscope slide for examination. Piperazine and pyrivinium chloride are therapeutically effective, but treatment is often followed by reinfection from the environment.

Epidemiology and control. Man is the only host of E. vermicularis. The eggs are resistant to drying and may contaminate clothing, bedding, and house dust, thus maintaining a constant source of infection in homes and institutions. The parasite is cosmopolitan. It is especially common in children, probably largely because their insanitary habits allow greater chances of spread. Treatment of cases is useful in control, provided sanitary measures are taken to minimize reinfection from the local environment.

Related species. Similar nematodes occur in many lower animals and are sometimes economically important as minor disease agents. Syphacia obvelata, a species found in rats and mice, is an occasional parasite of man and may readily be obtained for study from rodents. The eggs resemble those of E. vermicularis but are twice as large.

Trichuris trichiura. Trichuris trichiura is a frequent inhabitant of the cecum, appendix, and upper colon of man. The basic morphology of T. trichiura is similar to that of Trichinella spiralis, which is illustrated in an accompanying figure. The anterior three-fifths of the adult worm, containing he nonmuscular esophagus, is attenuated,

and the general appearance of the body has given rise to the common name "whipworm." Male and female worms are similar in size, 3 to 5 cm. long. The adult worms, embedded in the intestinal mucosa, have been accused of a role in the pathogenesis of appendicitis, but the evidence is inconclusive. Light infections are common throughout the population of the world's tropics and subtropics, are relatively without symptoms, and are unimportant to the infected individual. However, heavy infections, particularly in children, cause a hyperemic mucosa of the colon and rectum, chronic diarrhea, extensive inflammation, and rectal prolapse.⁸¹ Consistently effective drugs were not available until very recently, when it was shown that dithiazinine, a cyanine dye, is highly efficient in eliminating the worms from the intestine. The eggs passed in the feces are thick-walled, with a plug at either end, 53 by 22 μ in size. They are very resistant, surviving for months in contaminated soil. The embryos, undeveloped at the time of passage, require two weeks to several months, depending on temperature and humidity, to reach the infective stage. Ingested with contaminated food or water, they produce adult worms in the intestine. T. trichiura infection is world-wide but especially abundant in the tropics and subtropics because of poor sanitation and the effect of climate on development of the eggs.

Ascaris lumbricoides. Widely known simply as the "roundworm" of man, Ascaris lumbricoides is a large parasite of the small intestine. The white or flesh-colored females measure 20 cm. or more in length by 5 mm. in diameter, the males, 16 cm. by 3 mm. The characteristic eggs, 45 to 75 μ by 35 to 50 μ , have a smooth inner and a roughly tuberculated outer shell. They are undeveloped when passed in the feces. In soil or water they become infective in nine days or more, depending on environmental conditions. They may survive for several years despite drying, bacterial contamination, or adverse chemical conditions. Ingested in food or water they hatch in the intestine. The embryos, however, do not develop directly into adults in this site. Gaining access to the circulation they are carried to the lungs and escape into the air spaces. Via the trachea they reach the pharynx and are swallowed. Partial development occurs during the above migration. It is

completed in the small intestine, where egg-producing adults are found about two and one-half months after infection.

Passage of the migrating larvae through the lung may produce severe bronchopneumonia. Larvae filtered out of the circulation in abnormal sites induce inflammatory lesions. Adult worms in the intestine often cause no symptoms. Particularly in heavy infections, however, intestinal and nervous disturbances may occur, and intestinal obstruction occasionally results. Massive infection of children in the tropics is common with numerous fatalities prior to the availability of piperazine. The drug acts as a myoneural blocking agent for Ascaris and the paralyzed worms are eliminated by normal peristalsis as they are no longer able to maintain their position in the intestine. Consequently, chemotherapeutic methods now are effective in infections which previously necessitated surgical intervention to eliminate intestinal obstruction by worms. Various other injuries result from migration of the adult worms out of the normal habitat into the appendix, the bile ducts, the upper alimentary or respiratory tracts, the genitourinary system, or through the intestinal wall into the abdominal cavity. Hypersensitivity develops in infected persons and in laboratory workers who have handled the worms, and severe anaphylactic reactions may occur in such individuals.

Acquired immunity has not been observed in man, but experimental animals exhibit partial resistance to reinfection with related parasites. Antibodies are detectable by various tests after either infection or vaccination with worm extracts, and considerable investigation has been devoted to antigenic analysis. An allergic skin test has been used in diagnosis but is often positive in uninfected individuals who have acquired hypersensitivity from contact with the parasite. Laboratory diagnosis is preferably based on the finding of eggs in stools. However, a small proportion of cases harbor only male worms, and in such cases the immunological tests can be used.

Piperazine and hexylresorcinol are effective in removing the adult worms from the intestine. Some other drugs, particularly those used for treatment of hookworm infection, may cause migration of the adult Ascaris into abnormal sites.

Man is the only known host of A. lumbricoides. Infection predominates in children; that this results in part from age resistance is suggested by the marked age resistance of lower animals to related parasites. Infection is world-wide but most prevalent in the tropics and subtropics, where sanitary and climatic conditions favor its dissemination. Control depends on the reduction of soil contamination by proper sewage disposal and treatment of infected individuals. Raw vegetables are an important source of infection and should be thoroughly washed before consumption.

Related species. Cats, dogs, horses, and other lower animals harbor a number of closely related species. Rare human infections have been reported with at least three of these. A distinct race of A. lumbricoides causes severe pneumonitis in young pigs, known as "thumps." In man the eggs hatch and the larvae reach the lung, but adult worms do not become established in the intestine. Similarly, the human A. lumbricoides develops only to the lung stage in pigs. The adults of the pig Ascaris are easily obtained from slaughterhouses for laboratory study.

Visceral larva migrans. Visceral larva migrans has been recognized only recently as a clinical entity and the nematodes responsible are close relatives of Ascaris. The species most often involved are Toxocara canis and T. cati, the extremely common ascarids of the dog and cat. The larvae do not mature in man but wander extensively

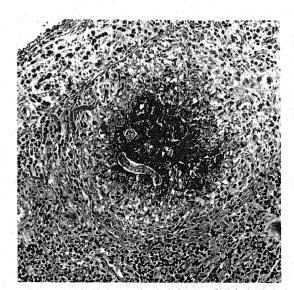

Figure 247. Human visceral larva migrans. Liver section showing granulomatous area containing *Toxocara canis* larva. × 105. (Beaver.)

through the tissues producing lesions and granulomata in the brain, eye, liver, lung, or other sites. The symptoms produced may be minor except for eosinophilia or may involve hepatomegaly, pulmonary infiltration, cough, hyperglobulinemia, and allergic manifestations.⁷⁷ Diagnosis is difficult but may be made on recovery of larvae in sectioned biopsy material with recognition of the larvae as shown in the accompanying figure. Serologic reactions are of value in diagnosis but give cross-reactions with Ascaris.85, 132 There is no specific therapy. Children with a history of dirt eating and an association with household pets run a risk of serious infection, emphasizing the need for anthelminthic treatment of dogs and cats.

Large nematode larvae causing eosinophilic granulomas and acute abdominal syndromes in man have been identified as Anisakis. This relative of the ascarid worms is generally considered to be a parasite of marine mammals, and in areas of Europe and the Far East where raw marine fish are eaten, this type of visceral larva migrans is being reported. 155, 170

Hookworms. The two important hookworms of man, Ancylostoma duodenale and Necator americanus, will be discussed together. Known since antiquity, human hookworms were first accurately described by

Dubini in 1843. Their relationship to disease was definitely shown by Perroncito in 1880, and the life cycle was elaborated by Looss.

Characteristics and life cycle. The adults of A. duodenale from the human small intestine are shown in the accompanying figure. The female measures 1 to 1.5 cm. in length by about 0.5 mm. in diameter. The double reproductive system coils abundantly throughout the body cavity. Two pairs of prominent unicellular glands are seen in the anterior half of the body, one excretory in function, the other secreting histolytic enzymes. The dorsally directed mouth is characterized by two pairs of ventral teeth (replaced in N. americanus by curved cutting plates). The male measures a little less than 1 cm. in length by about 0.4 mm. in diameter. The reproductive system shows a long, muscular ejaculatory duct, a prominent seminal vesicle, and a coiled testis. At the posterior end of the male worm is a broad, flat clasping apparatus, the copulatory bursa, composed of cuticle supported by finger-like rays of tissue. A. duodenale and N. americanus can be identified by details of structure of this bursa as well as by the differences in buccal teeth noted above.

The thin-walled eggs measure about 38 by 58 μ . Those of the two species of human hookworms cannot be distinguished micro-

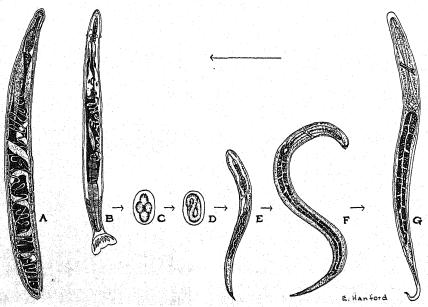

Figure 248. Life cycle of a hookworm, Ancylostoma duodenale. Note differences in magnification. A, female worm. B, male worm. C and D, eggs. E, first stage larva. F, second stage larva. G, infective larva. A and $B \times 10$. C to $G \times 250$. (Adapted from Looss.)

scopically from one another. They are usually in early stages of development upon escape from the body, maturing and hatching within 24 hours if conditions are favorable in the soil. The larva, about 0.25 mm. in length, feeds on fecal material and grows in three days or more to a length of about 0.4 mm. After molting it continues to grow until. by the fifth day or later, it measures about 0.6 mm. These two stages, characterized by a bulbous esophagus, are known as rhabditoid larvae. The third stage, resulting from a second molt, is a thinner form with a closed mouth and a less bulbous esophagus. It is usually still surrounded by a "sheath," the molted skin of the preceding stage. This is the filariform larva, the infective stage for man. It does not feed but may survive long periods in the soil under favorable conditions. If the infective larva comes in contact with human skin, it actively penetrates through the epidermis, reaches the circulation, and is carried to the lungs. Here, like the migrating larva of Ascaris, it breaks out into the air spaces and reaches the intestine via the trachea and esophagus. After two further molts, the worms are mature. Egg production begins about one month after infection.

Hookworm disease. Penetration of the skin by hookworm larvae produces a dermatitis known as ground itch or miner's itch. This is severe enough in some previously exposed individuals to be incapacitating. The adult hookworms live attached to the mucosa of the small intestine, feeding on blood and bits of tissue. They move about frequently, leaving bleeding wounds in the intestinal mucosa. The chronic loss of blood causes anemia and edema, resulting, in severe cases, in retardation of growth and mental development and in weakness and general debilitation.48 In many areas where hookworm disease is of importance, this anemia is intensified by virtue of the fact that nutritionally the population receives a relatively inadequate supply of available food iron. The additional loss of large quantities of blood and iron through hookworm infection produces the severe anemias often seen.125 Intestinal disturbances are seen in heavy infections. Death, except in infants and young children, is rarely a direct result of hookworm disease, but the condition often contributes to death from other causes. In white persons the symptoms are directly related to the intensity of infection, which,

because of the necessary development outside the body, is stable unless re-exposure occurs. Individuals with fewer than 25 N. americanus virtually never show symptoms. Those with between 25 and 100 worms show borderline effects. With more than 100 worms some clinical injury is almost always detectable. A. duodenale is more harmful, about half as many worms being required to produce a given effect. Normally, infection is maintained by constant re-exposure. In previously infected persons living under conditions which prevent additional infection, however, it has been shown that about one-half of the worms are lost in six months and about three-quarters in two years. A smaller number persist for as much as 12 years.

Immunity. Puppies can be largely protected against the dog hookworm by repeated small infections. Similar partial protection has been reported in a human volunteer. That antibodies are involved is shown by the fact that some protection is conferred on puppies by immune serum.

Diagnosis. Diagnosis hookworm of infection is based on recovery of characteristic eggs from the feces. Direct fecal smears were formerly used, but many infections with fewer than 25 worms are not detected with this method. Because the number of hookworms present in an infected individual is so important, several quantitative diagnostic methods have been devised. In the Stoll method a measured quantity (4 ml.) of feces is mixed with dilute NaOH solution (56 ml.), and all the eggs in a known sample volume (0.075 ml.) of this suspension are counted. The Lane method, or D.C.F. (direct centrifugal flotation), can be applied to lighter infections. One milliliter of feces washed by centrifugation is mixed with brine and recentrifuged with a coverslip on top of the tube. The eggs rise and can be counted on the coverslip. A relatively simple and accurate densitometric technique has also been devised.7 Figures obtained by either of these methods are expressed as the number of eggs per milliliter of feces. A single female N. americanus produces about 45 eggs per ml. of feces (about 6000 eggs per day) so that 25 worms (male and female) produce about 600 eggs per ml. and 100 worms produce about 2500 eggs per ml. A. duodenale produces about twice as many eggs per worm, but because of the greater pathogenicity of this species the egg output gives a roughly equivalent index of the severity of infection in both species.

A number of drugs are effective in eliminating hookworms from the intestine. The best at present are tetrachlorethylene and hexylresorcinol.

Epidemiology and control. Worms morphologically similar to N. americanus occur in pigs, but infection experiments indicate that they are distinct from the human hookworms. Man is the reservoir of infection with both A. duodenale and N. americanus.

There has been much study of the habits and requirements of hookworm larvae in the soil. The optimal temperatures are about 75° F. for A. duodenale and about 80° F. for N. americanus. Consistent high temperatures, about 100° F., are unfavorable. At 60° F. development is prolonged to two weeks or more, and below 50° F. there is little or no development. Continued temperatures below 40° F. kill the larvae. Moisture is essential to survival of the soil stages, but they die under water and are scattered by heavy rain. The type of soil is significant, probably largely in relation to its waterholding properties. Coarse sand and heavy clay are unfavorable, optimal development occurring in light sand or sandy loam. A large proportion of the infective larvae die within the first two weeks, but a few survive for several months under favorable conditions. Although lateral migration from the site of development is insignificant, the filariform larvae can move considerable distances vertically in the soil. Unless excessive drying occurs, they remain at the surface, where the chance of contact with human skin is greatest.

In addition to the environmental requirements of the larvae, various human factors affect the distribution of hookworm infection. Fecal disposal practices and the use of shoes are among the most important. All these factors combine to make hookworm infection a problem of the rural parts of warm countries. Exceptions occur in mines and tunnel-building operations, where local conditions may be favorable despite a generally unsuitable environment. N. americanus is the hookworm of central and southern Africa, the Western Hemisphere, and southern India. Throughout the rest of southern Asia it is mixed with A. duodenale. and a few foci of A. duodenale occur in South America. In most of Asia, southern

Europe, European mines, and North Africa only A. duodenale is found.

In the southern United States hookworm infection is most common in children, largely because adults are protected from infection by wearing shoes. That age resistance, if it exists at all, is a minor factor is shown by the fact that in countries where the whole population goes without shoes infection may predominate in adults. Racial immunity is marked, and Negroes under comparable conditions have fewer and less intense infections than do whites. Furthermore, Negroes seldom show clinical symptoms except in the presence of heavy infections.

Control depends on the reduction of soil contamination by treatment of cases and proper fecal disposal and on the prevention of contact between human skin and the soil. Chemical destruction of larvae in the soil has been of use only in particular cases. such as mines. Education is the major weapon in hookworm control, for the chief problems are sociological, and biological knowledge of the parasite is adequate to insure successful hookworm eradication if the habits of infected populations can be sufficiently influenced. Treatment of cases has an important place in hookworm campaigns. Formerly it was customary to treat all infected members of a community, or even the whole community (mass treatment), if sample diagnoses showed abundant and heavy infections. Current opinion favors treatment of only the clinically significant cases. In most regions the treatment of a small proportion of the population can eliminate most of the egg production.

Related nematodes of lower animals. Various animals harbor hookworms. Two species, Ancylostoma braziliense and A. caninum of dogs and cats, occasionally invade the skin of man. They are unable to develop further, and their wandering in the subcutaneous tissues produces a serpiginous dermatitis known as creeping eruption or cutaneous larva migrans. The adults of A. braziliense have been reported from man in the Far East. It has been claimed that the human cases harbor a distinct species, A. ceylonicum. Other, more distantly related parasites such as the numerous species of Trichostrongylus are disease agents of ruminants and are incidental parasites of man. One species, T. orientalis, is more common in man than in other animals. Heavy infections in man may produce diarrhea and high eosinophilia. The eggs resemble those of the hookworms but may be distinguished from them by their larger size and slightly different shape. The rat lungworm, Angiostrongylus cantonensis, has been found in human brain, where it causes a parasitic eosinophilic meningoencephalitis.³ In Asia and the Pacific islands this parasite is transmitted by the ingestion of raw land snails and slugs which are the intermediate hosts. It has been suggested that this organism is the cause of the "epidemic" eosinophilic meningitis of Tahiti.¹²⁶

Nippostronglyus brasiliensis (muris) of rats and mice is of interest because of extensive studies in the laboratory. Serum antibodies have been shown to exert a direct action on the parasites in vitro, and these antibodies together with tissue cells immobilize and destroy the larvae in the skin and lungs and destroy adults in the intestine.

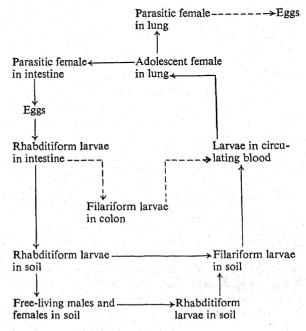

The first true cultivation of a parasitic worm has recently been accomplished with N. brasiliensis and Nematospiroides dubius. 164 Partial development of Necator americanus has been obtained. In a complex mixture of chick embryo extract, vitamins, amino acids, minerals, etc., the whole development of N. brasiliensis from the egg to the adult stage has been observed. While normal male and female worms were produced, the eggs produced were infertile. It is to be hoped that exploitation of this line of research will provide much needed information about parasitic worms.

Figure 249. Schematic life cycle of *Strongyloides stercoralis*. Broken arrows indicate rare or incompletely understood possibilities of development.

Studies have been made of the mechanisms involved in the exsheathment or cuticle shedding necessary between developmental stages of nematodes. The fluids responsible for this are believed important in stimulating the antibodies producing functional immunity to several of these infections. Extensive studies on the development of living nematode vaccines for use in veterinary medication are in progress, as in some forms it is believed that only antigenic stimulation by such metabolic products can produce significant immunity. 40, 142

Strongyloides stercoralis. Strongyloides stercoralis is a common intestinal parasite of man in warm countries. It exhibits a life cycle of extreme complexity, involving reproduction by adults in the soil as well as in the human intestine. Investigators working with different species of Strongyloides disagree on fundamental points, and it is not clear whether or not these disagreements result from specific differences in the worms studied.

Only female worms are known in the intestine of man. They are thin, transparent worms 2 to 2.5 mm. long by about 0.05 mm. in diameter. They lie buried in the mucosa of the small intestine, and the thin-shelled eggs are deposited in the tissues, where they hatch to release rhabditiform larvae very similar to those of hookworms. Escaping in the feces the larvae undergo one of two types of development. They may molt to filariform larvae which penetrate the skin

to establish infection. Alternatively, they may develop into the free-living males and females. The free-living female is stouter than the parasitic female and about 1 mm. long. The male is somewhat smaller, about 0.7 mm, in length, Eggs produced by the free-living female hatch to release rhabditiform larvae which may continue the freeliving cycle or may develop into infective larvae. The infective larvae, whether produced by free-living adults or developed directly from the rhabditiform larvae in the feces, penetrate the skin of man and reach the intestine via the circulation and lungs as in the hookworms. Male worms have not been found in the intestine, but "parasitic" males like those in the soil have been reported in the lung in abnormal hosts. Since investigation of a related species in rats has shown that a single infective larva can give rise to a female in the intestine producing fertile eggs, it is clear that the parasitic males are not essential in all species of Strongyloides. Oviposition in the lung has also been reported. A final complication is introduced by the reports that rhabditiform larvae might transform into infective larvae in the colon and penetrate its wall or the perianal skin to produce hyperinfections. The various paths of development indicated above are shown in the accompanying diagram. the dotted lines indicating phenomena which are incompletely known.

Penetration of the skin by the larvae causes dermatitis, and passage through the lung may give rise to bronchopneumonia. The parasitic females cause intestinal disturbances characterized chiefly by diarrhea. Laboratory diagnosis is based on identification of the rhabditiform larvae in the feces. These can be distinguished by the shorter buccal cavity from the rhabditoid larvae of the hookworms, which are occasionally encountered in fecal specimens. Dithiazanine is the most effective drug for therapy of S. stercoralis although not completely efficient in eliminating infection.

The epidemiology of S. stercoralis infection is similar to that of hookworm, and the same sanitary control measures apply. Dogs are infected with a strain indistinguishable from the form found in man and may be of some consequence in its maintenance. S. ratti of rats is a similar form which can produce local allergic manifestations in man and cutaneous eruptions similar to those of the hookworms.

Trichinella spiralis. The "trichina" worm. Trichinella spiralis, was first seen in human muscles at necropsy by Tiedemann in 1821. Leuckart and others worked out the life cycle.60 The adult forms are intestinal parasites of man and many other mammals, but their sojourn in the intestine is so brief that the more persistent larval infection in the muscles receives the main emphasis. The infective stage for man is a larva in the muscles of the hog. This stage is a minute coiled worm, about 1 mm, in length, enclosed in a lemon-shaped fibrous cyst, 0.25 by 0.5 mm. in dimensions. Ingested by a susceptible host the cysts reach the stomach, where the muscle and cvst wall are digested away. In about two days the larvae mature in the small intestine to adult males and females. The male is a thin, transparent worm about 1.5 by 0.04 mm. (Fig. 250). The anterior half of the body is occupied by a nonmuscular esophagus like that of the closely related Trichuris trichiura. At the posterior end are two pear-shaped clasping lobes. The female is about 4 by 0.06 mm, in size. After fertilization the females burrow into the mucosa where, after about one week, they begin to deposit minute larvae, about 0.1 mm. in length, in the tissues. These larvae reach the general circulation and are filtered out in the skeletal muscles, cardiac muscle, the central nervous system, and other sites. In most tissues they die, but in skeletal muscle they grow in about two weeks to the infective stage. One month after infection the larvae are surrounded by a fully developed cvst wall, produced by the host tissues. Much later, probably only after death of the larvae, these cysts become calcified, but they are known to remain infective at least for several months. Any skeletal muscle may be infected, but the larvae are most abundant in the diaphragm, intercostals, tongue, larynx, and eye muscles.

Meanwhile the adults have disappeared from the intestine. Most of the males die and are passed out within a week after infection. The females have largely disappeared within a month. It will be seen that the complete life cycle occurs in a single individual, for infective larvae are produced in the tissues of the same host which harbors the adults in its intestine.

an pron man infection in a population may be high, the usual infection with Trichinella is without detectable symptoms and the damage to the

host is probably insignificant. However, severe cases resulting from relatively massive infection occur and are characterized by two phases. Intense infection with the adult worms produces gastrointestinal disturbances, usually with diarrhea. Occasionally the injury to the intestine is so severe as to result in death within a few days after infection. Muscle invasion by the larvae leads to varied signs of toxemia, hypersensitivity, and muscle injury. Heavy infections cause death or chronic illness. The severity of the disease is proportional to the number of larvae ingested, and many mild cases undoubtedly escape detection.

Immunity to superinfection is demonstrable in experimental animals and can be transferred with immune serum. Some protection may be produced in the laboratory by vaccination with killed larvae, but this is insufficient to be of practical value. Direct action of immune serum on the worms has been described. Precipitin and skin tests are available using extracts of larvae digested out of infected muscle. These reactions are detectable two to three weeks after infection and remain positive for several years. Slide flocculation tests with antigen coated on bentonite particles or on cholesterol are the preferred immunological reactions for diagnosis. Like the complementfixation test they become negative a few months after infection and are thus indicative of current or recent trichinosis. The immunological and serological aspects of trichinosis have been the subject of a recent review which summarizes the numerous techniques which have been employed in diagnosis.83 Eosinophilia, often over 20 per cent, is characteristic and offers presumptive indication of trichinosis. Other diagnostic methods involve search for the larvae in body fluids or tissues. During migration they may be found occasionally in blood or spinal fluid, but it is often impossible to detect them. Muscle biopsies show the larvae in severe cases. There is no specific treatment for trichinosis. Supportive treatment and the use of ACTH ameliorates to a large extent the toxic febrile stage of this disease. In addition, there has been some use of thiabendazole, which suggests that it may be useful in treatment of this disease in the acute state.143

T. spiralis occurs principally in man, hogs, rats, and bears, although experimental infection has been produced in many species of mammals and birds. Human infection follows the consumption of undercooked pork (more rarely the meat of other animals, such as bears), while pigs acquire the parasite from garbage containing pork scraps or,

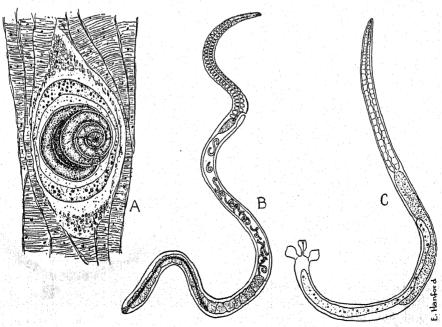

Figure 250. Trichinella spiralis. A, larva in muscle, \times 100. B, adult female, \times 50. C, adult male, \times 50.

less commonly, by eating carcasses of infected rats. Infection through the ingestion of larvae which pass out in feces has also been demonstrated and may be of some importance in the infection of coprophagous swine. In the United States as well as in the artic regions a significant sylvatic infection in carnivores exists. T. spiralis is worldwide in distribution, though infection in the tropics is rare. Various surveys in the United States, using routine necropsy examination of human diaphragms, have revealed a general infection rate of between 14 and 28 per cent despite the fact that very few clinical cases are diagnosed. 60 More recent studies indicate that the true incidence at present may be much less than this, more nearly approaching one-third of this figure.

Personal protection can be assured by thorough cooking of pork products, including hamburger of unknown composition. Government meat inspection does not attempt to detect Trichinella, for examination guaranteeing safety is considered impractical, but refrigeration for 24 hours at -18° C. destroys most of the larvae. Laws which forbid the feeding of raw garbage to hogs have been successful in reducing the incidence of infection. New methods of food preservation with gamma radiation show promise for control of trichinosis. Treatment of meat with radioactive cobalt renders the worms infertile, so that they cannot produce larvae. This prevents not only the systemic effects but also the intestinal pathology of early trichinosis.

THE FILARIA

Seven species of nematodes belonging to this group are important parasites of man. All produce motile embryos termed microfilariae which are produced in large numbers by the female in the host tissues and are released within a sheath (believed to be an elongate eggshell) or unsheathed. Microfilariae migrate or are carried by the circulation to the skin or to peripheral vascular beds, where they may be ingested by bloodsucking arthropods. Within this insect intermediate host the microfilariae transform without multiplication into infective larvae. become associated with the insect mouthparts, and may then be transmitted by the insect to the definitive host. After an incubation period and growth, which is little understood and may take as much as a year. the filaria may be found in their final sites of parasitism and are producing larvae. Wuchereria bancrofti and Brugia malayi adults parasitize lymphatic vessels; Onchocerca volvulus is usually in subcutaneous nodules or in deeper connective tissue as is Acanthocheilonema streptocerca. Mansonella ozzardi and Acanthocheilonema perstans are found in pleural or peritoneal cavities, while Loa loa as an adult migrates extensively through the connective tissues.

wuchereria bancrofti. Of the several species of filaria mentioned above, Wuchereria bancrofti is by far the most important. The disease, elephantiasis, was known in antiquity, but the larvae were first seen in 1863 by Demarquay and the adults by Bancroft in 1876. Manson, in 1878, showed that development of the larvae took place in mosquitoes. This discovery is noteworthy because it represents the first incrimination of an insect in the transmission of disease.

Characteristics and life cycle. The adults live coiled in the lymph nodes of man. They are thread-like translucent worms, the female 7 to 10 cm. long by 0.25 mm. in diameter, the male 4 cm. by 0.1 mm. The egg, covered by a thin membrane, hatches in the uterus or in the host tissues to release an active embryo about 0.2 mm. long. This embryo, known as a microfilaria, escapes into the lymph and enters the circulating blood by way of the thoracic duct. In most regions the embryos of W. bancrofti show

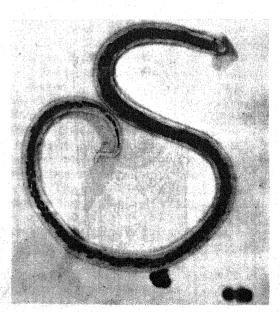

Figure 251, Microfilaria of Wuchereria bancrofti in thick blood film. × 300.

marked nocturnal periodicity, occurring in the peripheral blood almost exclusively at night. In many of the South Pacific islands, however, they appear in the blood at all hours. Extensive study has failed to provide a satisfactory explanation of this periodicity, although there is suggestive evidence that daytime activity induces accumulation of the microfilariae in capillaries of the lung. 63

The microfilaria develops no further in the circulating blood. If ingested by a susceptible mosquito, however, it undergoes a series of transformations in the tissues of the insect. Within a day the larva leaves the stomach of the mosquito and invades the thoracic muscles. Here it develops into a stout "sausage larva," which, after a second molt, elongates to form the infective stage, a thin worm 1.5 to 2 mm. in length. This infective larva leaves the muscles and migrates to the proboscis sheath of the mosquito, arriving six days or more after the infective blood meal. When the mosquito takes a new blood meal, the infective larva, apparently stimulated by the warmth of the skin, breaks out of the proboscis sheath and penetrates the skin, probably through the wound caused by the biting mosquito, to establish infection in man. The early development of the worms in man is not known, but microfilariae appear in the circulating blood several months after infection. In the related species, Brugia malayi (see below), development to the adult stage requires about 80 days in experimental animals. Although the longevity of the adult worms in the lymphatics has not been determined, they probably live for several vears.

Filariasis. The adult worms are most prevalent in the lymph nodes of the inguinal region, but they are also found in lymphatics elsewhere in the body, they induce inflammation and fibrosis in the infected nodes. The consequent restriction of lymph flow causes edema, lymphangitis, lymphadenitis, and elephantiasis. Secondary infection of the lymphatics with streptococci and staphylococci is often significant. Long-standing cases sometimes show enormous enlargement of the scrotum, vulva, legs, or breasts.

Evidence of acquired immunity is lacking, but complement-fixing antibodies are detectable in the serum, and skin tests are positive in infected individuals. The reactions are group-specific, occurring with extracts of filarial worms from lower animals and giving false positives in other

nematode infections. Laboratory diagnosis is preferably based on the identification of microfilariae in fresh blood preparations or stained thick blood films. They are often not detectable in early infections or in long-standing cases with much tissue damage. Other filarial worms infecting man (see below) also produce microfilariae in the circulating blood, but these can be differentiated microscopically from the larvae of *W. bancrofti*.

Certain antimony compounds, notably Neostibosan and Anthiomaline, eliminate microfilariae from the blood of cases for long periods. Hetrazan, an oral drug, is more effective and less toxic and has been widely used, principally because of its ease of administration and its ability to minimize mosquito infections by eliminating microfilariae in the human reservoir. It is not known whether these drugs kill the adult worms in man, but they destroy the adults of other filarial worms in experimental animals.

Epidemiology and control. Man is the only known host of the adult worm. A large number of mosquitoes of the genera Culex, Aedes, Mansonia, and Anopheles support development of the larvae, but the most important are Aedes polynesiensis in the South Pacific islands, Anopheles gambiae in West Africa, and Culex quinquefasciatus (C. fatigans) elsewhere. There is an interesting correlation between the habits of the mosquito hosts and the periodicity of the microfilariae discussed above. Aedes polynesiensis bites by day, and it is in the regions where this mosquito transmits W. bancrofti that the microfilariae are found in the peripheral blood at all hours. In other regions, where the principal vectors attack. man in the evening or at night, the microfilariae show a marked nocturnal periodicity.

W. bancrofti is a parasite of warm countries, occurring widely throughout the tropics and subtropics. Climate favors the production of mosquitoes and the development of larvae of W. bancrofti in the insect, and the poorer housing of the tropics permits greater contact between mosquitoes and man. The slow development of human infections, the lack of multiplication of W. bancrofti in the mosquito hosts, and other hazards combine to limit dissemination of the parasite. As a consequence the infection seems to die out in an area unless there are many human cases and abundant mosquitoes. The former endemic center in the United States, around Charleston, South Carolina, where the incidence was 20 to 30 per cent before 1920, now shows no cases. Control is a matter of mosquito reduction, protection from mosquito bites, attention being directed to the habits of the particular vectors in any area, and chemotherapy of cases.

Other species of filarial worms. Brugia malayi is very similar to W. bancrofti and is widely distributed in southeast Asia, the China Sea area, and Eastern India, often occurring with W. bancrofti. In some areas it is transmitted by mosquitoes of the genus Mansonia whose larvae obtain oxygen from subaquatic vegetation, posing additional problems of control. A similar parasite, B. pahangi, of Malaya is common in wild and domestic mammals and, in man, may produce the symptoms of tropical eosinophilia.

Onchocerca volbulus is widely distributed through central Africa, and in the Western Hemisphere has been introduced into Guatemala, Mexico, Venezuela, and Surinam. 120 The adults are found in tightly coiled masses in subcutaneous nodules of connective tissue where commonly they may be extirpated by minor surgery. Others may be deep-seated and not palpable. The microfilariae are not found in the circulating blood but concentrate in the skin, where they may readily be demonstrated by superficial biopsy. In the Western Hemisphere nodules containing the adults are found on the head, and the microfilaria cause ocular lesions commonly leading to blindness. Sensitization reactions are usual in infection with Onchocerca and may be pronounced following chemotherapy with Hetrazan.

Blackflies of the genus Simulium, whose larvae must develop in fast-flowing mountain streams, serve as intermediate hosts. Since man is the only known definitive host, attempts have been made to provide control by surgical removal of the onchocercal nodule plus chemotherapy. Intravenous Suramin (Naphuride sodium) is effective.

Loa loa is found in the subcutaneous tissues of a variety of primates including man and is limited to West and Central Africa, where it is transmitted by the biting deerfly Chrysops. It has been called the "eye worm" because of the frequency with which it may be found passing under the conjunctiva of the eye surface, and it is also associated with a fugitive "calabar" swelling presumed to be due to reaction of the host to the metabolic products of the migrating

adult worm. The microfilariae are diurnal, in the peripheral circulation, and unsheathed.

Acanthocheilonema streptocerca is found in the dermal and subcutaneous connective tissue and its unsheathed microfilariae are in the superficial layers of the dermis. It is limited in distribution to parts of Central Africa, A. perstans has a wide distribution in tropical Africa and is also present in coastal areas of South America and the West Indies. Its microfilariae are nonperiodic and unsheathed, and are found in the peripheral blood. The adults are found associated with the peritoneal cavity, in mesentery, in retroperitoneal tissues, in the pericardium, or occasionally in subcutaneous cysts. Infections are often without symptoms but may be associated with sensitization phenomena and rarely with more serious or fatal complications. Mansonella ozzardi is also found the tropical areas of the Western Hemisphere, occupies body cavities, and has circulating, unsheathed, nonperiodic microfilariae. No symptoms are associated with infection. Both species Acanthocheilonema and Mansonella of are transmitted by gnats of the genus Culicoides.

There are numerous filarial worms of mammals and birds widely distributed over the earth. One of these, Dirofilaria immitis, is an important pathogen of dogs, the adult worms living in and occluding the vessels of the heart. Antigen prepared from Dirofilaria has been used in intradermal and serological tests for the diagnosis of filariasis in man. The specificity of the reactions is low. Litomosoides carinii, a parasite of the body cavity of the cotton rat, is a form commonly used in laboratory investigations.

Dracunculus medinensis, the Guinea worm, is a common parasite of man in the Middle East, Africa, India, and Indonesia. It was also endemic in the tropics of the Western Hemisphere but has not been recently reported. Although a tissue parasite resembling the filaria, it does not have a true microfilarial stage. The small male worms are rarely seen. The females, after several months' development in internal connective tissues, appear in the subcutaneous tissues, usually of the leg. They are large worms, averaging about 1 meter in length, often visible through the skin as they lie in the tissues. The skin of the host ulcerates at the anterior end of the worm, and larvae escape, usually when the leg is subtuffer to 1854 the letter of

merged in water. These larvae develop in copepods, e.g., cyclops, and human infection follows ingestion of the parasitized copepods in drinking water. The human infection, possibly the "fiery serpent" of the Bible, is associated with severe sensitivity reactions immediately preceding initial blister formation and larval release by the female. In some regions the female worm is gradually removed from the tissues by rolling it up on a stick. Local injection of phenothiazine is said to be effective in therapy, and antihistamines may be used to relieve the sensitivity phenomena.

Chapter Thirty-five

RICKETTSIA

The name rickettsia is applied to a group of very small, gram-negative coccobacillary microorganisms which includes the etiological agents of the typhus fevers, spotted fever and related diseases, and tsutsugamushi disease of the Far East.5, 54, 70 They were first observed by Ricketts in 1909 associated with Rocky Mountain spotted fever. Those found in the bodies of lice taken from typhus fever patients by da Rocha Lima in 1916 were named by him Rickettsia prowazeki in honor of Ricketts, who had died in 1910 of typhus fever during an investigation of that disease, and of von Prowazek, another early worker in the field who died of typhus. Closely similar microorganisms are found as the cause of heartwater disease in cattle and of other diseases of lower animals, including sheep and dogs, and also, as apparently nonpathogenic forms, in the sheep ked, Melophagus ovinus and from Haemaphysalis and Dermacentor ticks.9

Relation to bacteria and viruses. rickettsiae are of special interest, not only as the causative agents of human disease, but because they appear to represent transitional forms between the bacteria on the one hand, and the viruses on the other. As described elsewhere (Chap. Nine), the bacteria may be arranged in a series, from the purely saprophytic nonpathogenic forms through those which are saprophytic but pathogenic because they form potent toxins, to the closely adapted parasites which make up the majority of the disease-producing bacteria. Many of the last have fastidious nutritive requirements, reflecting limitations in synthetic abilities, and certain forms, especially Pasteurella tularensis and Bartonella, grow within the host cells, but all of these, with exceptions such as the leprosy bacillus and the spirochetes of syphilis and related diseases, are cultivable on lifeless mediums.

The rickettsiae, like the viruses, are set apart from the bacteria by their inability to grow in the absence of the living host cell, necessitating culture in the embryonated egg or in some other form of tissue culture. While it is a reasonable inference that they are dependent upon the host cell for essential metabolic reactions rather than essential metabolites, the rickettsiae do show limited metabolic activity and resemble the bacteria in having a similar cell structure and multiplying by a process of binary fission. They are related to the viruses through the organisms of the psittacosis group for which there is evidence for the occurrence of fission during replication, but which contain only fragments of enzyme systems, viz., cytochrome C and folic acid. It is perhaps relevant that infections with rickettsiae and the psittacosis group are susceptible to treatment with the antimicrobial chemotherapeutic drugs, while the diseases of viral etiology are not.

Although fragments of enzyme systems, such as flavin and biotin, are associated with certain of the poxviruses, and adenosine triphosphatase activity is apparently an integral part of one of the avian leucosis viruses, most other viruses show little or no evidence of independent metabolic activity. Also, there is no evidence that any of these replicate by a process similar to fission. Rather, the viral particle seems to develop by differentiation within a morphologically discrete portion, or matrix, of the protoplasm of the host cell as in the case of the poxvirus and related viruses, or final assembly seems to occur just prior to ex-

826 RICKETTSIA

trusion of the complete viral particle from the host cell as in the replication of influenza virus (Chap. Four).

The rickettsiae, then, although occupying an intermediate position, seem to be more nearly related to the bacteria than to the viruses, but whether such a graded series of microorganisms has phylogenetic implications is another matter (Chap. Seven).

Morphology. These microorganisms may appear either as cocci or short bacilli, 0.3 to 0.5 μ long and 0.3 μ in breadth, but bacillary forms as long as 2 μ may occur, and filamentous forms have been described. The cells occur singly, in pairs perhaps to be associated with binary fission, and often in dense irregular masses, within affected cells, particularly those of mesothelial origin which line the serous cavities. Some species are found only in the cytoplasm, but others, such as those of the spotted fever group, occur in the nucleus as well. They are nonmotile and do not show obvious capsules.

In electron micrographs of isolated rickettsiae prepared in the usual way there appears to be a dense central portion surrounded by a peripheral area of less dense material, but when the preparation is fixed with osmic acid, or is a section of infected tissue, the dense central portion is not differentiated. A well-defined cell wall is present and demonstrable in electron micrographs. Staining. The rickettsiae stain poorly or not at all with the usual bacterial stains but are readily stained with Giemsa, are stained red against a blue background with Macchiavello's stain (basic fuchsin, citric acid, and methylene blue) and a light blue against a pink background with Castaneda's stain (buffered methylene blue and safranine counterstain). They may also be stained with Wright's stain in tissue sections to give a blue nucleus and pink cytoplasm. The coccoid and coccobacillary forms stain uniformly, but bipolar staining of the bacillary forms is not uncommon.

Chemical composition. The chemical composition of typhus and Q fever rickettsiae is closely similar to that of most bacteria. There is some uncertainty as to the precise amounts of the various components present because of possible, or even probable, loss during purification procedures such as, for example, ether extraction and washing. Preparations not treated with ether have given about 30 per cent protein. 47 per cent lipid including 30 per cent neutral fat and 17 per cent phospholipid, and 12 per cent nucleic acid. The lipid figure is in contrast with that of 12 to 13 per cent found in ether-extracted and washed preparations, but it is uncertain as to whether the differential represents contamination or rickettsial lipid removed by the extraction. The nucleic acid fraction contains both the deoxypentose and pentose types, in a ratio of

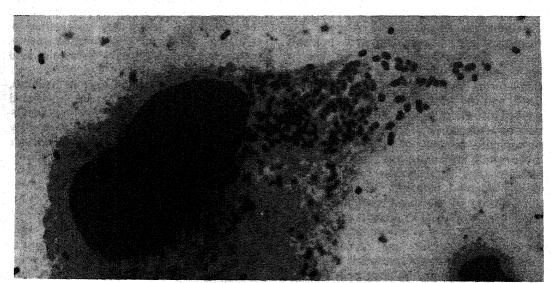

Figure 252. The rickettsiae of tsutsugamushi in scrapings from a mesothelial surface of an infected guinea pig. Note the coccobacillary forms, often paired, and their intracellular location. \times 2000.

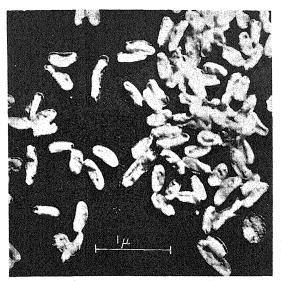

Figure 253. Electron micrograph of Q fever rickettsiae purified by elution from a cellulose anion exchanger. (Hoyer *et al.*²⁶)

about 2:1, with relatively constant amounts of DNA, but variable amounts of RNA from one preparation to another. Cell wall preparations from rickettsiae lysed with deoxycholate resemble bacterial cell walls in composition, containing amino acids and a polysaccharide moiety hydrolyzing to glucose, galactose, hexosamine, and glucuronic acid. The close similarity to bacterial cell walls is also indicated by the demonstration of muramic acid, probably in association with mucopeptide, in rickettsial cell walls. 52

Physiology.¹⁵ The occurrence of independent metabolic reactions of rickettsiae has been noted above. Largely through the work of Boyarnick, Wisseman, and others, it has become clear that these microorganisms carry out glutamic-aspartic acid transamination and oxidize glutamic acid via the citric acid cycle. It has been found also that glutamate oxidation can lead to the phosphorylation of hexose and the formation of adenosine triphosphate from the diphosphate. The formation of glucose-6-phosphate is catalyzed by a hexokinase which is similar to hexokinase from other sources. 50 A terminal respiration mechanism is indicated by the presence of flavin-iron-porphyrin catalysts. The available evidence suggests that the Krebs cycle may be operative, and pyruvate the chief energy source.47 Folic acid is present and a possible function is suggested by the synthesis of serine from glycine and formaldehyde in the presence of tetrahydrofolic acid⁴⁶ by the Q fever rickettsia. There is evidence too that host-independent pyrimidine synthesis may occur.⁴¹

These activities are not stable and the conditions effecting their inactivation and reactivation are of considerable significance. On storage in isotonic salt solution in the cold, rickettsiae lose the ability to carry out the above reactions and at the same time lose toxic and hemolytic activity (see below) and infectivity. It has also been known from early work on spotted fever by Parker and others that the rickettsiae in starved ticks are avirulent but become virulent after the tick is fed or incubated at body temperature. Loss of toxic and hemolytic activity also occurs at 36° C. in the absence of metabolizable substrate.

In the first two instances, physiological activity, toxic and hemolytic activity, and infectivity are restored by incubation of the microorganisms with NAD and/or coenzyme A.^{11, 12} Para-aminobenzoic acid has a rickettsiostatic effect (see below), and this inhibitory effect is also reversed by NAD.²⁵ The inhibitory effect of PABA is thought to be due to the formation of a PABA-NAD complex, thus preventing dehydrogenase activity, and reactivation occurs when exogenous NAD is added to the system.

Inactivation of toxic and hemolytic activity at or near body temperature is possibly different. It is prevented in the presence of glutamate, pyruvate, or ATP, and reactivation occurs on incubation with glutamate and inorganic phosphate and is increased by ATP, the gain or loss of activity being correlated with ATP. Evidence such as the foregoing provides a rational basis for the nature of the suspending medium, a sucrosephosphate-glutamate solution, used for rickettsiae.

Cultivation. As indicated above, the rickettsiae grow only in the presence of, and probably invariably within, host cells. They will grow on the chorioallantoic membrane of the embryonated hen's egg, but usually produce only small numbers. As first shown by Cox, they grow readily and profusely in the yolk sac of the embryonated egg, and this method of culture has been one of the most widely used.

They also grow in various kinds of tissue culture. In modified Maitland medium, proliferation of the rickettsiae is not associated with active cell metabolism, as is

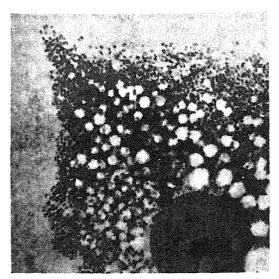

Figure 254. Rickettsia prowazeki in an infected cell from chick endoderm cultured in vitro. Most of the cytoplasm of the cell is occupied by rickettsiae. × 1500. (Weiss.)

usually the case with the viruses, but rather with a low metabolic rate of the host tissue, and proliferation is most rapid as the host cells begin to die. Active multiplication has, in fact, been observed in dead chick embryos which contain some surviving cells.

Several species of rickettsiae have been studied in cultures of mouse fibroblast tissue culture, using a cell line (MBIII) that grows in roller tubes as a dispersed suspension of individual cells.13 The rate of growth was relatively slow, with a generation time of about 16 hours, which compares with the short generation time of rapidly multiplying bacteria of 20 minutes or less, and the longer generation time of 30 hours or more of slow-growing bacteria such as tubercle bacilli. Studies of growth in rat fibroblast culture in the living state by phase microscopy have made possible the direct observation of the occurrence of binary fission.60 It was also observed that, following intracellular multiplication, the microorganisms are extruded from the host cells in association with a process of extension and retraction of microfibrils at the surface of the cell. It is probable, however, that rickettsiae are usually released by degeneration and dissolution of the host cell. Cultures of explants of the endodermal cells of the chick yolk sac have also been used for the cultivation of rickettsiae.72,76 and may be used for quantitative titration of infection, at least with the Q fever rickettsiae, because

foci of infected cells are readily observed in stained preparations and may be counted.

Resistance. The resistance of the rickettsiae to deleterious influences is generally of the same order as that of the more delicate bacterial vegetative cells. They are killed by the usual disinfectants but, like some of the viruses, are resistant to glycerol, and by heating at 55° to 60° C. for 30 to 60 minutes. The Q fever rickettsiae are said to be somewhat more resistant to heating, and these and the typhus fever rickettsiae are relatively resistant to drying, persisting in viable infectious form in the airborne state in the first instance, and in infected louse feces in the second, for considerable periods.

Pathogenicity. The rickettsiae appear to be well-established parasites of arthropods, and there is good evidence for the acarinid origin of the rickettsial diseases. They are not pathogenic for the insect vectors that transmit them, except lice, and, in fact, the infection is congenital in insects undergoing an incomplete metamorphosis, e.g., ticks. They also appear to be reasonably well adapted to certain animals, especially rodents, which in many instances constitute a reservoir of infection in nature.

The characteristic pathological changes found in rickettsial disease result from the multiplication of the microorganisms within the endothelial cells of the small blood vessels throughout the body, and especially in the skin and brain in the case of typhus fever. Proliferation of affected cells, and thrombosis following injury to the lining of small vessels, is common. Inflammatory cells accumulate around areas of vessels, and in severe infections in man and guinea pigs, e.g., those of spotted fever, the smooth muscle cells of the vessel media may be involved, and extensive thrombosis can lead to gangrene.

Toxin. Two kinds of rickettsial toxicity are demonstrable, the one an endotoxin associated with the intact microorganisms^{6, 16} and the other a hemolytic activity which lyses sheep and rabbit cells but not those of a number of other species examined. The endotoxin is lethal for mice and is titrated by intravenous inoculation of material such as yolk sac culture, with deaths up to 18 hours attributable to toxicity. The titer of the toxin is directly proportional to the number of rickettsiae present and is correlated with their viability. Most agents that destroy infectivity also inactivate the toxicity, with the exception of ultraviolet

radiation which, in appropriate doses, selectively reduces infectivity without affecting toxic, hemolytic, or respiratory activity.2 The activity of the toxin is similar to that of other microbial endotoxins and increases vascular permeability but appears to differ in other respects.78 It is specifically neutralized by antiserum, with cross-reactions between members of the main groups of rickettsiae, the typhus, spotted fever, and tsutsugamushi groups (see below), but not between groups. There is also an exotoxic activity demonstrable by intradermal inoculation of the rabbit to produce a local inflammatory reaction and by enlargement of the liver and spleen of rats and mice on intraperitoneal inoculation.

The hemolytic activity of suspensions of purified rickettsiae is species-specific, as noted above, and is closely associated with both endotoxin and enzymatic activity, particularly the oxidation of glutamate, and its activity is inhibited by metabolic inhibitors. Ordinarily hemolytic activity of the causative microorganism does not play an appreciable part in the pathogenesis of infectious disease, but is concerned in fatal rickettsial toxemia in the rabbit also, the animals showing massive intravascular hemolysis, with hemoglobinemia, hyperkalemia, myocardial damage, and hypotension. It is not clear, however, that either the toxicity or hemolytic activity plays any significant part in the pathogenesis of rickettsial infections, for they appear to be dissociable from virulence.55

Experimental infections. Rickettsial infection may be produced in the guinea pig, the usual procedure in isolation being the intraperitoneal inoculation of 5 ml. of blood into each of two animals. A febrile attack occurs in seven to 12 days, and some varieties of rickettsiae produce a characteristic orchitis or scrotal reaction which has differential value. An acute fibrinous exudate is formed in the scrotal sac, and many cells packed with rickettsiae may be found. The disease in the guinea pig is often not fatal, and this animal is much more resistant to infection than is man. Other common laboratory animals are more resistant, and rats, mice, rabbits, dogs, cats, etc., may show no febrile reaction or other outward manifestation of disease, though the infection has been established and in some cases, at least, may persist for months.

Chemotherapy. Sulfonamides and penicillin are ineffective in the chemotherapy of the rickettsial diseases, although they have been used in the past in the treatment of complications such as bronchopneumonia and other secondary bacterial infections. Para-aminobenzoic acid has been found to be partially effective in typhus and spotted fevers if given early, but cannot be regarded as a really effective chemotherapeutic agent. With the development of the broad-spectrum antibiotics effective chemotherapy of the rickettsial infections has been made possible, for these substances have been found to be effective chemotherapeutic agents for this group of diseases. Chloramphenicol has been of particular interest in the treatment of tsutsugamushi disease (scrub typhus), since effective prophylactic immunization of man is not yet practical and the mite reservoir of infection is not subject to adequate control. Largely through the work of Smadel and his co-workers63 it has been found that the clinical disease may be suppressed by prophylactic or therapeutic administration of this substance but that relapse occurs unless the treatment is continued for about four weeks; apparently the antibiotic alone does not suffice to eliminate rickettsiae from the tissues, but an immune response is required also. The tetracyclines have been found to be even more effective chemotherapeutic agents.

It has been of considerable interest that, although drug-resistant strains of rickettsiae have not yet been found in nature, Weiss and his colleagues have been able to develop resistant strains in the laboratory. Strains of *R. prowazeki* resistant to the rickettsiostatic activity of PABA, quinoxaline, and

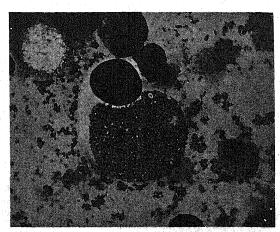

Figure 255. Rickettsiae of Q fever in a smear of skin exudate. Note the macrophage packed with enormous numbers of the rickettsiae. × 1125.

erythromycin have been produced by serial egg passage in the presence of increasing concentrations of the drug.^{73, 74, 75} Most, but not all, of the resistant strains did not appear to be altered in virulence and toxicity.⁷¹

Immunity. Recovery from an attack of rickettsial disease usually confers a solid and lasting immunity. In at least some instances this is associated with the prolonged survival of the microorganisms in the body as indicated by the occurrence of Brill's disease (see below) and the demonstration of tsutsugamushi rickettsiae in clinically recovered individuals.

The development of artificial immunization procedures will be considered later, but it may be noted here that the immune response is manifested by the appearance of protective antibody, of opsonins and agglutinins for the rickettsiae, and of complement-fixing antibody. The last has been of a good deal of interest as a differential diagnostic method and distinguished even closely related varieties of rickettsiae. Antibody neutralizing the toxicity of typhus rickettsiae occurs also and is used in the United States as the basis of assay of immunogenic potency of vaccines. The rickettsiae contain both somatic and capsular antigens. In the purification of yolk sac culture the material is extracted with ether to remove lipid material, and, with the exception of R. orientalis, the rickettsiae are found in the aqueous phase. The extraction results in the liberation of soluble, group-specific antigen in the aqueous phase which has been found to be stripped-off capsular material.

The Weil-Felix reaction. In some rick-

ettsial diseases agglutinins appear to certain strains of Proteus. This apparently anomalous response was observed by Weil and Felix in 1915 and has very considerable diagnostic value. They found that a strain of Proteus vulgaris, which they designated X-2, was agglutinated by typhus serums, and another strain, designated X-19, was similarly agglutinated but to much higher titer; in fact, titers as high as 1:50,000 are occasionally observed in European typhus. It was further shown that the agglutinating antigen was a part of the heat-stable somatic or O antigen; these strains are, therefore, commonly termed OX strains. Other strains showing this immunological characteristic have been isolated since. It is of some importance that an O antigen be used in carrying out the agglutination because antibody to the flagellar antigen of Proteus occurs with some frequency in normal serums. More general application of this agglutination test, commonly known as the Weil-Felix reaction, showed that it is specific for the typhus group of fevers, serums from other rickettsial diseases agglutinating only to low titer or not at all. The phenomenon is a consequence of the presence of a common antigen in the typhus rickettsiae and the X strains of Proteus.

The Proteus agglutinin is only a part of the antibody response. It is not identical with the rickettsial agglutinin for the latter appears earlier, persists longer, and appears to be associated with protective antibody. Furthermore, the opsonin remains in typhus serum after it has been absorbed with Proteus.

The SECREPT AND A COURSE OF THE PARTY OF THE

Immunological (Weil-Felix) Grouping of Rickettsial Diseases*

	IMMUNOLOGICAL GROUP	
OX-19 OX-19 ++++ OX-2 + OX-K —	OX-K OX-19 – OX-2 – OX-K ++++	Undetermined OX-19 + OX-2 + OX-K +
Classic, European typhus Brill's disease Endemic murine typhus of United States, Australia, Greece, Syria, Manchuria, Malay (shop ty- phus), India, Burma, Philip- pines, Hawaii, Toulon (fièvre nautique)	Tsutsugamushi of Japan, Formosa, Malay, Netherlands East Indies "Scrub typhus" or "rural typhus" of Malay, N.E.I., French Indo-China, India, Australia Mite fever of Sumatra	Spotted fever São Paulo typhus Fièvre boutonneuse Fièvre exanthematique Febbre errutiva Tick fever of South Africa Kenya fever Tick typhus of India

^{*}Modified from Felix.

Another immunological type of Proteus, the OX-K strains, was found to be agglutinated by tsutsugamushi serums but not by typhus serums. This, coupled with the OX-19 type, makes possible the division of the rickettsial diseases into three groups: the typhus group, in which OX-19 is agglutinated; the tsutsugamushi group, in which OX-K is agglutinated; and the spotted fever group, which is indeterminate in that neither type of Proteus is agglutinated to high titer. A classification of the rickettsial diseases on this basis is given in the accompanying table.

The significance of the Weil-Felix reaction is wholly unknown. The occurrence of one common antigen, or more specifically a polysaccharide haptene, in two such different microorganisms might be a matter of chance. The occurrence of a second common antigen, shared by another variety of Proteus and another group of rickettsiae. on the basis of chance alone is improbable. There is no evidence, however, which points to any other connection between Proteus and the rickettsiae. There is, for example, no association between the X strains and typhus; X strains are found in diseases other than typhus, and Proteus strains other than X strains are found in typhus. Proteus infections, of course, often result in the formation of specific agglutinins. It has been found, for example, that the serums of persons infected with Pr. vulgaris, Pr. mirabilis, or Pseudomonas aeruginosa will agglutinate OX-K strains of Proteus to a high titer. Such persons might be said to give a positive Weil-Felix reaction.

Specific serological reactions. An accurate method of serological diagnosis and identification should be based on the use of rickettsial antigen and thus a true immunological specificity. Although it has been extremely useful, the Weil-Felix reaction is not a specific reaction and is not completely reliable. The protection test in the guinea pig is useful in the demonstration of antigens functional in effective immunity, but the relatively greater natural resistance of these animals as compared with that of man tends to blur differentiation in some instances. There is, for example, a significant adequate cross-protection between louseborne and murine varieties of typhus rickettsiae in the guinea pig, but not in more highly susceptible man. Similarly, the protection test does not differentiate between strains of O fever rickettsiae.

The *in vitro* serological reactions, made practicable by the availability of relatively large amounts of antigen from yolk sac culture, are of two kinds, the one direct agglutination of rickettsiae in suspension, and the other complement fixation. Two kinds of antigen are present, group-specific soluble antigen and strain-specific antigen present in the microorganisms.

Yolk sac cultures contain large amounts of lipid material which is removed by ether extraction of a saline suspension of the yolk sac material. As indicated above, all the rickettsiae except the tsutsugamushi rickettsiae, which are found in the interphase emulsion, remain in the aqueous phase, and the treatment releases soluble antigen from all of these except Q fever rickettsiae. The soluble antigen can be separated by spinning out the rickettsiae in the centrifuge and used in a precipitin test, or the mixture of rickettsiae and soluble antigen can be used as an antigen in the complement-fixation test.

Difficulty has been experienced with some antigen preparations in that they tend to give false positive complement-fixation reactions. especially with Wassermann positive serums. This is not true of suspensions of washed rickettsiae, but these are difficult and laborious to prepare. Satisfactory soluble antigens may be prepared from infected yolk sacs purified by ether extraction, followed by treatment with benzene and precipitation with sodium sulfate. Complement-fixation with antigen does not give false positives with Wassermann positive serums, but does not always distinguish between epidemic and murine typhus.

The fluorescent antibody technique has been applied to the demonstration of rickettsiae by the direct method, 14, 33 and to the titration of antibody by the indirect method. Troublesome cross-reactions in the latter, as between murine and epidemic typhus, are largely eliminated by the simple expedient of diluting the serum to be tested in heterologous soluble antigen. 22

Classification. The intermediate position of the rickettsiae with respect to other microorganisms has been described above, but it is also apparent that differentiation occurs within the group. In general, the rickettsiae pathogenic for man fall into four groups. Three of these are well defined with respect to immunological character and pathogenicity but are heterogeneous with

respect to insect vectors. These are the rickettsiae responsible for the typhus group of fevers, those of the spotted fever group, and the causative agents of tsutsugamushi disease. There is some confusion as regards the names of diseases caused by these forms because a number of the spotted fever group of diseases have been given names such as "tick typhus." The rickettsiae causing Q fever and trench fever are set apart from the other rickettsiae, but are unrelated to one another, and make up a miscellaneous group.

Within the typhus group, two species are distinguished, R. prowazeki and R. typhi, the causative agents of epidemic louseborne or European typhus, and of murine typhus respectively. Four species are distinguished within the spotted fever group: R. rickettsii, the causative agent of spotted fever, São Paulo typhus, and Tobia fever; R. conori, the causative agent of Boutonneuse fever and the probable causal agent of tickborne diseases occurring in Africa, India, and Siberia under the general name of tick typhus; R. australis, the causative agent of Australian tick typhus; and R. akari, the causative agent of rickettsialpox. The tsutsugamushi rickettsiae are immunologically heterogeneous, but subgroups or species have not been distinguished, and these agents are given the single name R. tsutsugamushi.

The apparent causative agent of trench fever is poorly known, and the designation *R. quintana* is not based upon a detailed differential characterization. The causative agent of Q fever has, however, been characterized with some precision and is set apart from the other rickettsiae sufficiently that it has been given a different name, *Coxiella burnetii*. The occurrence and differential characteristics of these rickettsiae are summarized in the accompanying table.

The rickettsiae found in lower animals are also thought to differ from the human pathogens sufficiently to warrant different names: Cowdria ruminatum for the causative agent of heartwater disease, and others causing disease of lower animals are designated Ehrlichia, including Ehrlichia ovina found in sheep, E. canis found in dogs, and E. bovis found in cattle. The rickettsia-like nonpathogenic microorganism is found in the sheep tick and, unlike the rickettsiae cultivable on glucose-blood agar, has been named Wolbachia melophagi.

The Typhus Fevers 34

The typhus fevers constitute a group of closely related infections which occur in various parts of the world. The incubation period is five to 18 days, and the clinical picture is essentially the same in all the typhus fevers, though the severity of the disease varies widely. There is an initial violent headache which persists with the onset of chills and higher fever. A macular eruption appears soon after the fourth day which remains until defervescence. Crisis occurs at about the twelfth day, and recovery may be more or less complete at the end of another two weeks, though the cough which develops may persist, and mental vigor may remain somewhat impaired for some time. The complications include typhus gangrene, which is perhaps associated with the circulatory disturbances arising during the disease, a highly fatal bronchopneumonia, otitis media, and typhus encephalitis. Death rarely occurs before the end of the first week. The case fatality is

highly variable; it has been as great as 70 per cent in some epidemics, and 20 to 30 per cent is not uncommon, while in endemic typhus it is much lower, perhaps 5 per cent. Typhus is almost always a considerably milder disease in children than in adults.

Two species of rickettsiae are responsible for these diseases, and characteristically occur in the cytoplasm but not in the nucleus of invaded cells. They are associated with two epidemiologically different types of typhus fever. One is the classic European or epidemic typhus and the etiological agent is R. prowazeki (R. prowazeki var. prowazeki). The other is murine typhus, sometimes called endemic typhus, and the causative rickettsiae is R. typhi (R. prowazeki var. mooseri, R. muricola, R. mooseri). Both are immunologically homogeneous, and strains from all parts of the world appear to be substantially identical. These rickettsiae may be distinguished from one another by complement fixation and contain both common and individual antigens.

EPIDEMIC LOUSEBORNE TYPHUS FEVER

The classic form of typhus fever known for many years is the louseborne typhus of Central Europe, which persists in endemic foci in Russia and Poland and has occasionally broken out in major epidemic form from time to time during periods of stress. The disease is associated with overcrowding and filth and has been termed "camp fever" and "jail fever." Epidemics are not infrequent in both civil and military populations during time of war and may become very extensive; it is estimated, for example, that 315,000 persons died of typhus in Serbia in 1915 and that 25 million cases occurred in Russia in 1917 to 1921.

The disease is transmitted by the human body louse, Pediculus vestimenti. The head louse may also transmit the infection, but its importance in the spread of the disease is not established. During the febrile stage of the disease, rickettsiae are present in the blood, and the louse is infected by ingestion of blood. In the louse the rickettsiae infect the cells lining the gut, multiply, and are discharged in the feces after rupture of the infected cells, the louse becoming infective in six to eight days at 32° C. The salivary glands are not infected, congenital transmission of the infection does not occur, and the louse is eventually killed by the infection.

Most human infections are probably acquired by contamination of the louse bite with infected feces, but infection via the mucous membranes is possible. The rickett-siae persist in viable form in dried material such as louse feces, and accidental laboratory infections have occurred following inhalation of infectious materials.

Although bedbugs and ticks have been experimentally infected, it is probable that the louse is the sole vector of the disease under natural conditions.

Brill's disease. Louseborne European typhus of a mild type is endemic, though in late years decreasing in prevalence, in cities along the Atlantic Coast in this country. Long regarded by many as different from European typhus, Brill's disease has been shown to be louseborne and identical

with European typhus. In this country it has presumably been imported from endemic areas in Europe. It has also been found in Australia⁶⁹ in immigrants from Central Europe. Brill's disease, or latent typhus, has been observed in Europe, both in England³¹ and on the continent. Such latent typhus, or healthy carrier state, capable of infecting lice fed upon the infected individual, may provide the starting point of epidemics. Russian workers tend to discount such a source of infection, considering that apparent recurrence is a consequence of reinfection rather than relapse.⁵¹ Since the infection is not congenitally transmitted in the louse, and infected lice usually die within two weeks, it seems probable that the reservoir of infection occurs in man.⁵⁶ Such a reservoir of subclinical infection in Egypt, for example, is indicated by serological surveys.1 The reservoir known to exist in Central Europe may consist in part of latent infections, but the disease smolders in endemic form in relatively large numbers of mild infections. For example, an overall incidence of 24.5 per cent of positive Weil-Felix reactions was reported in healthy Russians with no history of typhus in the German-occupied area of Russia in World War II, rising from 11 per cent in the less than five-year-old group to 34.5 in the sixto 10-year-old group.

MURINE TYPHUS

The type of typhus fever which prevails in the southern United States and in Mexico, where it is known as *Tabardillo*, was long assumed to be a mild form of louseborne European typhus. The disease is associated with rats, and it has since become apparent through the investigations of a number of workers that the rat is a reservoir of infection in both this country and Mexico and that the disease is transmitted from rat to rat and from rat to man by the rat flea, *Xenopsylla cheopis*, and by the rat louse, *Polyplax spinulosa*.

The disease may also be transmitted by the human louse and, when a case occurs by transmission from the rat in a community where there are lice in abundance, it has been suggested that murine typhus may become an epidmic louseborne infection. Such epidemics occur from time to time in Mexico. Murine typhus occurs with considerable

836 RICKETTSIA

frequency in this country; approximately 20,000 cases were officially recorded from 1932 to 1941, and 5191 cases with 214 deaths were reported in 1945 from 44 states but predominantly from the southeastern states. Prior to 1946 it was generally believed that murine typhus was an under-reported disease in this country. Since that year it has been apparently declining rapidly, with 685 cases reported in 1950, 46 cases in 1961, and 28 in 1965. With attention directed toward the disease, fallacious diagnosis appears to have become more common, largely as a result of misinterpretation of low-titer Weil-Felix reactions. With the advent of specific complement fixation, many reported cases are not confirmed by this method. In a study in the southeastern states it was shown, for example, that 25 per cent of reported cases were definitely not typhus.58 A degree of control of the disease is possible by reduction of rat and rat flea populations, as indicated by a study in Georgia in which the incidence of human disease was reduced by 80 to 90 per cent.36

Murine typhus also occurs elsewhere in

the world and is known by various names. The urban type occurring in Malaya or "shop typhus," the mild form of the disease in the Mediterranean region known as Toulon typhus, and other infections such as Moscow typhus, Manchurian typhus, and the Red Fever of the Congo are all murine typhus identical or nearly so with the type found in the United States and Mexico.

Clinically murine typhus does not differ appreciably from the classic European type. It is sometimes said that the European disease is likely to be more often fatal, but this does not appear to be true; both forms are equally fatal in epidemic form and relatively mild in the endemic form.

Differences between R. prowazeki and R. typhi are demonstrable but not great. The murine rickettsiae produce a necrotic scrotal reaction in guinea pigs, while the European variety does not; the murine variety may be carried indefinitely in mice without alteration, but the European variety tends to degenerate; the rickettsial pneumonia and intraperitoneal multiplication in rats with the production of enormous numbers of

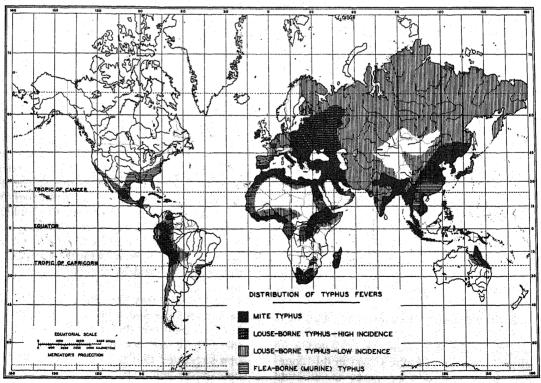

Figure 256. The world-wide distribution of typhus fevers, including classic or European typhus, murine typhus, and mite typhus of the Far East. (Redrawn from maps prepared by Army Medical Intelligence. Based on Goode Base Map No. 201M. By permission of the University of Chicago Press.)

rickettsiae may be produced by the murine variety but not by the European type alone. There is a slight immunological difference also, for, while recovery from either infection results in a solid and lasting immunity to both, murine vaccines protect against murine infection but only incompletely against infection with the rickettsiae of European typhus. The two may be differentiated by the complement-fixation test.

IMMUNIZATION

The preparation of vaccines which will produce an effective active immunity to typhus fever is a matter of some importance, since under the circumstances in which it occurs in epidemic form adequate control of the vector is often not possible. In man the immunity produced by immunization is specific, and the cross-immunity between epidemic and murine typhus is not of a sufficiently high order to be practical.

Inactivated vaccine. Rickettsiae have been grown in a number of ways for preparation of inactivated vaccines. Weigl vaccine was one of the first and was prepared from the bodies of lice infected by intrarectal inoculation. A vaccine prepared from the infected mouse brain has been used also. R. typhi produces a pneumonia in rats on intratracheal inoculation, and rickettsiae may be recovered in large numbers from infected lung tissue by differential centrifugation. The rat is not susceptible to this kind of infection with R. prowazeki unless its resistance is reduced by prior treatment such as x-irradiation. These methods were largely supplanted with the introduction of yolk sac culture for the preparation of vaccine in the early 1940's.

Of these the Weigl vaccine is impractical for use on any scale. Vaccine prepared from rat lung culture has been used to a considerable extent in Mexico and by the German army during World War II; the method of preparation of such vaccine, involving as it does intratracheal inoculation, is inherently highly dangerous and also relatively expensive.

The vaccine currently used in the United States is yolk sac vaccine, prepared by ether extraction as noted above, and the final preparation is a suspension of formalin-killed epidemic typhus rickettsiae and soluble antigen. There is some reason to believe that the

liberation of soluble antigen increases the immunogenic potency of the material. It is standardized on a toxicity basis, *i.e.*, prevention of the toxic effect of inoculated rickettsiae. It has been used in the United States Army, given as a course of three doses at seven- to 10-day intervals, followed by a single dose every four to six months. The possibility of allergic reactions following inoculation of the egg material has not proved to be important; approximately six to eight million troops received vaccine with only two fatalities attributable to it.

Experimental evidence strongly suggests that a marked degree of immunity is produced by immunization with this inactivated vaccine. There is no good field test of its efficacy, though only a very few cases of mild typhus and no deaths were recorded in the United States Army during World War II in spite of the exposure of many to the disease. There have been a number of instances of infection of vaccinated and unvaccinated laboratory personnel, and it is clearly apparent that immunization substantially modifies a subsequently acquired infection and the resulting disease is mild.

Vaccines prepared Attenuated vaccine. with attenuated microorganisms of sharply reduced virulence for man are a necessity in those instances in which the inactivated antigen will not produce an effective immunity, e.g., tuberculosis and yellow fever, or are desirable in those cases in which the induced immunity is of a low order as in plague. Multiplication of the attenuated microorganism provides a larger amount of antigen, undenatured by inactivation processes, and possibly additional antigenic substances formed during growth (Chap. Fifteen), but the possibility of reversion to virulence persists in the use of such vaccines.

In the case of R. prowazeki, a spontaneous change to avirulence for guinea pigs and other laboratory animals occurred during continuous egg passage of a strain isolated in Madrid and designated strain E. The possibility of this attenuated strain giving a superior effective immunity has been of considerable interest, and has been studied by Russian workers^{57,82} and by Fox and his associates in this country. 19, 20 In the latter studies human volunteers were used and subjected to extensive field trial in Peru, where the disease is endemic. Complementfixing and toxin-neutralizing antibodies are produced in more than 90 per cent of persons inoculated under field conditions. The im838 RICKETTSIA

mune response was shown to be associated with an effective immunity demonstrable by challenge inoculation with virulent *R. prowazeki* and to persist for more than six years

after immunization. There has been no indication of a reversion of the attenuated strain to virulence, nor do inoculated persons appear to serve as foci of infection.

The Spotted Fevers

The rickettsial diseases which make up the spotted fever group are considerably more heterogeneous than those of the typhus fever group. Several of them are but poorly understood as yet. All are transmitted by ticks, although some differ immunologically and clinically from Rocky Mountain spotted fever.³⁰

Rocky Mountain spotted fever. Clinically Rocky Mountain spotted fever resembles typhus fever; the rash is generally more extensive and the nervous symptoms may be more pronounced, but in areas where both diseases prevail it is exceedingly difficult to distinguish them on clinical grounds alone.

The disease has been known for many years in the Rocky Mountain region in states such as Idaho, Montana, Wyoming, Oregon, and Washington. In 1930, however, it was found in the eastern part of the United States in the South Atlantic states such as Maryland, Virginia, West Virginia, and North Carolina. Although the disease is not limited to these regions, of the 2190 cases reported from 1933 to 1937, 65.5 per cent were from the Mountain and Pacific states and 27.4 per cent from the South Atlantic group; the two areas combined accounted for 93 per cent of the total cases reported in the country. Approximately 200 to 300 cases are reported each year; 219 cases were reported in 1961, and 281 in 1965.

It is customary to speak of two types of the disease, an eastern type and a western type. Both are, however, immunologically identical and are caused by the same rickettsia, R. rickettsii, which, in contrast to the typhus rickettsiae, is found within the nucleus of invaded cells. Both are transmitted by ticks, but by different species. The wood tick, Dermacentor andersoni, is the vector of the disease in the western states, and the dog tick, Dermacentor variabilis, transmits the disease in the Atlantic region. The rabbit tick, Haemaphysalis leporis-palustris, disseminates the infection in the animal population. Amblyomma americanum, A. cajennense, D. occidentalis, Rhipicephalus sanguineus, D. parumapterus, and Ornithodorus parkeri are able to transmit the disease experimentally and are to be regarded as potential vectors. The infection is congenital, i.e., is transmitted from one generation to the next, in D. andersoni, but whether it is congenital in the dog tick is not clear. In the first instance, then, there need be no animal reservoir of infection although it is probable that animal reservoirs of infection occur.53,62 In the second, the dog may serve as a temporary reservoir of infection. The body louse may be infected experimentally with these and other rickettsiae of the group,77 but seems to play little or no part in the human disease.

The case fatality of spotted fever is highly variable. In Idaho it has been about 4 per cent, in western Montana about 20 per cent, and in certain regions of the Bitterroot Valley as high as 90 per cent. Over the country as a whole, however, the rate is 18 to 19 per cent. It is generally said that the disease is milder in the Atlantic region than in the Mountain states, but over a period of years there is little difference in case fatality; for the period of 1933 to 1937 the case fatality in the Mountain and Pacific states was 19.4 per cent and for the South Atlantic states 18.1 per cent.

Spotted fever was transmitted to guinea pigs and monkeys by Ricketts in 1907. Guinea pigs show a febrile reaction, the spleen is enlarged, and the necrotic scrotal reaction occurs. R. rickettsii is immunologically related to the typhus rickettsiae, but the titer of cross-reaction in the complement-fixation test is not high enough to cause confusion; there is also a small degree of cross-protection between the two.

Other spotted fevers. Closely similar tickborne disease has been observed in Central and South America; in Central America and Brazil it is known as São Paulo typhus, and in Colombia as Tobia fever. The causative rickettsiae are very closely related to, if not identical with, R. rickettsii. There seems to be no doubt that these diseases are spotted fever, and there is some tendency to refer to them collectively as American spotted fever.

Immunization. A solid immunity is associated with recovery from spotted fever, and an effective prophylactic immunity may be produced by inoculation with vaccine. The first vaccine was that prepared by Parker and his associates at the United States Public Health Service laboratory in Montana. It consisted of infected tick tissue inactivated with phenol and was used for more than 15 years. Subsequently it was displaced by formalin-inactivated vaccine of rickettsiae grown in yolk sac culture. These vaccines produce an effective immunity in experimental animals such as guinea pigs.

Vaccines are standardized for immunogenic potency in guinea pigs, *i.e.*, for active protection as measured by the average number of days of fever during the 12 days after challenge, and serum antitoxin 10 days after vaccination by passive protection of the mouse against toxin challenge. Active mouse protection against toxin challenge correlates well with the guinea pig test.⁸

While the incidence of the disease is too low to allow adequate field test, there is evidence that the naturally acquired disease in man is either prevented or modified by prophylactic immunization.

RELATED RICKETTSIAL INFECTIONS

There are a number of diseases of rickettsial etiology which are closely related to the American spotted fevers and which are known as tick typhus or tick fever and identified by the locality in which they are observed. The causative rickettsiae have been shown in some cases to be closely related to, but apparently not identical with, R. rickettsii, while others which are not this well known show clinical and epidemiological features which suggest a closely similar etiology.

Boutonneuse fever. This disease, also known as fièvre boutonneuse and Marseilles fever, is prevalent in the Mediterranean area, and is caused by *R. conori*. This rickettsia is immunologically related to, but separable from, *R. rickettsii* by toxin neutralization as well as by other serological methods. Cross-protection is practically complete in convalescent guinea pigs, but immunization with *R. conori* vaccine will not protect against *R. rickettsii* infection,

and immunological differences are also demonstrable by the complement-fixation test.

The animal reservoir of infection is the dog, and the disease is transmitted by the tick, *Rhipicephalus sanguineus*, in which the infection is congenital. The disease is milder than American spotted fever, with a case fatality rate of 1 to 2 per cent. It is distinguished clinically by the small, local, indurated lesion with a necrotic center which develops at the site of the tick bite,³² and is known as the eschar or tache noire, and by regional adenopathy.

Other tick fevers. The tick-bite fevers of Africa, including Kenya fever or Kenya typhus and South African tick fever, together with Indian tick typhus, appear to be substantially the same disease as boutonneuse fever, although there is no eschar in Kenya fever. In Africa the infection is found in a number of ticks, including *Haema*physalis leachii, Amblyomma haebreum, Rhipicephalus appendiculatus, and R. sanguineus, and the last is found infected in India also. Kenya fever is transmitted by R. sanguineus, but more often by the larvae of A. haebreum. While these vectors constitute a reservoir of infection, there is also evidence that a reservoir may be present in wild rodents.

North Queensland tick typhus. This disease, occurring in Australia, was first described in 1946. The causative rickettsia is immunologically related to the spotted fever rickettsiae but is sufficiently distinct that it has been designated *R. australis*. The evidence for tick transmission is as yet circumstantial but suggests that *Ixodes holocyclus* is a vector of the disease.

Siberian tick typhus. This is a relatively mild rickettsial disease, occurring in Central Asia and extending to the eastern coast of Siberia. The causative rickettsia is closely related to *R. conori*, but differentiable from it,²⁴ and has been called *R. sibericus*. The disease is believed to be transmitted by several ticks, including *Haemaphysalis concinna*, *Dermacentor sylvarum*, and *D. nuttallii*

RICKETTSIALPOX

Rickettsialpox was first observed in New York City in 1946, when 124 cases were reported, and subsequently has been found in urban areas on the eastern seaboard of this 840 RICKETTSIA

country. It has also been reported to occur in urban areas in Russia and has been isolated from wild rodents in Korea.²⁷ The disease is a mild febrile illness, characterized by a local lesion at the site of infection, and a varicelliform rash. It is rarely if ever fatal.

The causative agent is a rickettsia of the spotted fever group which is immunologically related to *R. rickettsii*, but may be distinguished from it; it has been given the name *R. akari*. The animal reservoir of infection is the wild house mouse, *Mus musculus*, and the disease is trasmitted by the mite *Allodermanyssus sanguineus*. The causative agent has been isolated from mice and mites as well as from patients' blood, and the human infection is apparently acquired

from the bite of infected mites. R. akari is pathogenic for both wild and laboratory mice and for the guinea pig. A fatal disease is produced in the mouse following intraperitoneal inoculation; the infection may be transmitted by spleen or brain, and the rickettsiae are demonstrable on microscopic examination of scrapings from the peritoneal cavity, as from the surface of the spleen. A febrile disease and scrotal reaction are produced in the guinea pig.

R. akari is readily cultivable in the embryonated hen's egg, in the amnionic cavity or the yolk sac. Yolk sac antigen fixes complement in the presence of patient's serum, but also cross-reacts with spotted fever

antibody.

Tsutsugamushi Disease (Scrub Typhus, Mite Typhus) 18, 40, 68

A disease of rickettsial etiology prevalent in the Far East is known as tsutsugamushi disease (dangerous bug disease), Japanese flood fever, or Kedani fever in Japan, as mite typhus in Sumatra, and as rural typhus or scrub typhus in Malaya. The last two are not to be confused with shop typhus of Malaya, which is murine typhus. The disease is very similar to spotted fever in its distribution and clinical picture but differs in the latter respect in that there is a primary sore and adenitis as in fièvre boutonneuse, and the symptoms include headache, orbital pain, a maculopapular rash, and fever. As in spotted fever, the case fatality rate varies widely, from 0.5 per cent to perhaps as high as 60 per cent in some areas such as Korea. The disease is characterized immunologically by a Weil-Felix reaction in which the O antigen of the OX-K strains of Proteus are agglutinated but the OX-19 strains are not.

The causative microorganism has been variously named R. tsutsugamushi, R. nipponica, R. orientalis, and R. akamushi; the first, R. tsutsugamushi, is the name commonly used. Strains are closely related immunologically but are readily differentiated by complement fixation. There seems, however, to be no clear serological differentiation into types, and the strains also differ in virulence and in degree of adaptation to egg culture. These rickettsiae are apparently quite unrelated to R. sennetsui, 4, 21 isolated in Japan from a glandular fever type of disease in man.

The strains commonly used as antigens

are the Gilliam and Karp strains, and sometimes the Seerengavee strain; serums from some cases are predominantly of one type or another, while others react to about the same titer with all three. The Gilliam strain is toxic to mice while the others are not, and the toxicity is not neutralized by antiserums to other strains of R. tsutsugamushi, or to only a slight degree. R. tsutsugamushi may be grown in the yolk sac or chorioallantois of the developing hen's egg, in tissue culture, and in the lungs of rats. Since this rickettsia occurs in the emulsion phase in ether extraction of yolk sac culture, the material may be purified by extraction before saline dilution or by differential centrifugation for the preparation of complement-fixing anti-

Experimental animals recovered from nonfatal infection show practically complete cross-immunity among strains of R. tsutsugamushi. Immunization with vaccine is a difficult matter, however, for apparently subcutaneous inoculation does not protect, but intraperitoneal vaccine protects against intraperitoneal challenge. Formalinized tissue culture vaccine or rat lung vaccine has been used for successful immunization of experimental animals. Killed vaccines are ineffective in man, but Smadel and his coworkers, 35, 64, 65 have produced an effective immunity with living vaccine given together with chloramphenicol to provide protection against infection. At present, however, active prophylactic immunization of man is not practical because of lack of cross-protection between the various strains of the rickettsiae.

Q FEVER 841

Tsutsugamushi occurs over a wide area in the Asiatic Pacific region, including Japan, Korea, Formosa, Indo-China, Malaya, Burma, Assam, New Guinea, and the Philippine Islands. It appears to persist as an infection of rodents and of mites and is transmitted to man by mites. The vertebrate host and insect host and vector differ somewhat from place to place. In Japan the rodent host is the field mouse, Microtus montebelli, and the disease is transmitted by the larvae of Trombicula akamushi. In Sumatra the vertebrate hosts are the house rat, Mus concolor, and the field rat, Mus diardii, and in Assam and Burma the wild rat, Rattus flavi-

pectus yunnanensis, and the tree shrew, Tupaia belangeri versurae, Except in Japan the most important insect vectors appear to be Trombicula deliensis, a mite very closely related to T. akamushi, Trombicula walchi which is regarded by some as identical with T. deliensis, and Trombicula fletcheri. The mites occur in low, damp areas of grass, underbrush, and scrub, in Japan along uncultivated banks of rivers, and the infection is thus restricted to certain localities. In the temperate climate of Japan the disease has a seasonal incidence, but in tropical regions there is no strict seasonal distribution of the disease in man.

Q Fever 39, 59

Q fever* was described in Australia in 1937 as occurring in slaughterhouse workers, and the causative agent was shown to be a rickettsia. What proved to be a closely similar, if not identical, rickettsia was isolated by Davis in the United States from ticks, and the disease it produced in guinea pigs was called nine-mile fever. When the Australian and American strains proved to be substantially identical, the disease was called American Q fever in this country, but, since the microorganism has been found to be of world-wide occurrence, the geographical designations have been dropped.

This microorganism is set apart from the other rickettsiae in a number of its characteristics. The American strains were found to pass bacteria-proof filters, and the rickettsia was named R. diaporica for that reason, but the name R. burnetii given the Australian strains had priority. It fails to form a toxin, is more resitant to heat and drying than the other rickettsiae, and is unique within the group, in that arthropod transmission is not an essential link in its dissemination. It is immunologically distinct from the other rickettsiae. In general, it appears to be sufficiently different from the other rickettsiae causing human disease to justify giving it independent generic status, and it is known as Coxiella burnetii.

Like the other rickettsiae, it grows profusely in the yolk sac of the embryonated hen's egg and may be cultivated in various kinds of tissue cultures. Guinea pigs may be infected, and the infection is either symptomless or accompanied by a febrile reaction, but there is a specific immunological response. There appear to be two kinds of antigens present in C. burnetii strains, distinguished by differences in the time required to reach peak titer of complement-fixing antibody in the infected person, and the strain is said to be in phase I or phase II;48 phase I antigen has higher protective potency as vaccine. 49 Complement-fixing antigen is grown in the yolk sac, and it is important to use a strain which will react with both kinds of antibody: the Henzerling and nine-mile strains have been used extensively for this purpose.

Disease in man. The disease in man is a febrile respiratory illness, with an incubation period of 14 to 26 days, and the infection is usually acquired by inhalation of infectious material. It characteristically takes the form of atypical pneumonia and is responsible for an appreciable portion of illness diagnosed clinically as primary atypical pneumonia, with pneumonic involvement demonstrable by x-ray examination in even mild cases. There is often evidence of liver involvement, headache is a predominant symptom, and there is no rash, but convalescence is apt to be protracted. Complement-fixing antibody is present in convalescent serums, and a hypersensitivity to intradermal vaccine may develop.29

The human disease is widespread, occurring in all major geographical areas, 10 as shown both by diagnosed illness and by the prevalence of serum antibody found in surveys. The largest number of cases has been reported from this country and various parts

^{*}The assumption that Q fever refers to "Queensland fever" is a misconception; in the original reports it refers to "Query fever."

842 RICKETTSIA

of Europe, especially in the Mediterranean area where the disease is known as epidemic hiberno-vernal bronchopneumonia or Balkan grippe, and occurred in Allied military forces in that area during World War II.

Infection in lower animals. The Australian studies showed the existence of a relatively intricate host-parasite relationship. There C. burnetii is maintained in wild animals, especially the bandicoot (Isoodon macrourus), and is transmitted by the ticks Haemaphysalis humerosa and Ixodes holocyclus. Cattle may be infected by these ticks, and in turn the cattle ticks Boophilus microplus and H. bispinosa may become infected. The rickettsiae occur in large numbers in the feces of infected ticks and survive for long periods in the dry state. The contamination of cattle hides with such infected feces, and the inhalation of this dust, is regarded as the probable mechanism of infection of slaughterhouse workers in Australia. The disease also occurs among slaughterhouse workers in this country, but the way in which the infection is contracted is uncertain.

Infection in dairy cattle is very widespread

over the United States, with herd infection rates ranging from 1 to 65 per cent.³⁷ C. burnetii is constantly present in the milk from such herds and is shed into the environment in infected placentas at parturition. Inapparent infection in dairy workers as reflected serologically is substantial, and parallels the incidence of infection in cattle.³⁸ Pasteurization of milk suffices to destroy the rickettsiae, but the margin of safety is very narrow, and the microorganism is occasionally found in pasteurized milk.¹⁷

The observations of Lennette and his colleagues have shown that in northern California the infection is maintained in sheep herds by contamination of the environment by milk and infected placentas taken at lambing time, and is reflected in a seasonal increase in human disease. It is probable that infection occurs by inhalation of contaminated dust. Similar observations have been made elsewhere. 42, 43, 66 There is also serological evidence 67 for the occurrence of reservoirs of infection in domestic fowl and wild birds, and their ectoparasites.

Trench Fever

In the course of the First World War a specific infection became known by the name of trench fever or Wolhynian fever. It is said to have caused almost one-third of all the illness in some of the armies in northern France and occurred also in Mesopotamia and Saloniki. It appeared again in the Second World War in the German army in Russia.28 It has a long incubation period (six to 22 days); the most constant symptom is pain in the legs; the fever is often high and of the relapsing type. Recovery is the rule. The disease can be transmitted to healthy men by the intravenous injection of whole blood taken from patients up to the fifty-first day of the disease.

Natural transmission is chiefly, if not solely, through the body louse. The bites of infective lice appear to be the most important element in producing trench fever, but the infectious agent is also present in the excreta and may enter through abrasions in the skin caused by scratching. The infectious agent is present in the urine of patients and is said to remain active for a long time in dry louse feces and dried urine.

The association of rickettsiae with the dis-

ease was established in 1919 by Arkwright and his co-workers on the basis of the infectiousness of lice, or louse excreta, containing very large numbers of the microorganisms following feeding on infected persons. The rickettsia, known as R. quintana or R. pediculi, has not been cultured, multiplying apart from man only in the stomach of the louse, and the disease has not been produced in experimental animals. Patients' sera agglutinate rickettsiae from the louse stomach, and diagnosis is based on the louse-feeding test, or xenodiagnosis.⁴⁴

In the original studies it was found that the blood remains infectious for lice, and the lice for human volunteers, for some months after disappearance of symptoms. Subsequently it has been found that the infection may persist for years, with relapse as long as 19 years after the initial illness, 45 which may be diagnosed by the louse-feeding test.

The causal relation of the rickettsia to the disease cannot be considered as fully established, but available evidence provides a strong presumption that such a connection obtains.

Laboratory Diagnosis of Rickettsial Disease³

Laboratory diagnosis is an indispensable adjunct to the identification of disease of rickettsial etiology and involves two general kinds of procedures; the one isolation and identification of the causative agent, and the other serological identification of serum antibody. The latter also allows retrospective diagnosis and estimation of prevalence of infection by surveys for antibody.

The isolation of rickettsiae is of limited diagnostic utility because of technical complications and inherent dangers. Guinea pigs and mice are the animals of choice and may be inoculated intraperitoneally with blood taken during the febrile stage of the disease. As described earlier, there may be little overt evidence of infection in the guinea pig with some kinds of rickettsiae, and blind passage, using spleen emulsion as the inoculum, may be required. In addition, blood may be taken and examined for serum antibody, indicating an immune response in symptomless infection.

The antibody response may be assayed nonspecifically by the Weil-Felix reaction, and specifically, using rickettsial antigen, by complement fixation, rickettsial agglutination, toxin neutralization except in the case of C. burnetii, and protection of experimental animals against known challenge inoculum. Of these, the last two are not practical for routine application, and by far the most commonly used serological reactions are the Weil-Felix reaction, which almost any laboratory may carry out, and the complement-fixation and/or rickettsial agglutination reactions. The first serves to identify or exclude the broad groups of rickettsiae but is diagnostic for the tsutsugamushi group; the complement-fixation reaction is group-specific but may be made specific or relative species titers may be diagnostic; and rickettsial agglutination is applicable in field studies and is regarded as more species-specific in some instances, e.g., the typhus fevers, than the unmodified complement-fixation reaction.

Weil-Felix reaction. The agglutination of OX-19, OX-2, and OX-K strains of Proteus allows provisional identification of the typhus groups of rickettsial disease but does not differentiate among the other rickettsial infections, and irregular results may occur within the so-called indeterminate, or Weil-Felix negative, groups of infections.

Normal serums from persons living in endemic localities often show an agglutinin titer of 1:50, and titers as low as this are regarded as negative, 1:100 as suggestive, and 1:200 as diagnostic. The Weil-Felix reaction shows an anamnestic response in a number of febrile diseases, especially typhoid fever. In typhoid fever, however, the titer of the Weil-Felix reaction does not continue to rise after the first week, whereas typhoid bacillus agglutinin continues to rise in titer. In rickettsial disease the agglutinin titer appears relatively early, reaching a titer as high as 1:400 by the end of the first week, and rising to 1:1600 or above by the end of the second week. It drops thereafter, falling to 1:400 or less by the eighth or ninth week after onset, and has no utility in retrospective sero-diagnosis. Though classified as an indeterminate type, spotted fever frequently shows a considerable agglutinin titer for Proteus, and differentiation from murine typhus may be difficult when the two diseases occur in the same area.

Specific serological reactions. Although in certain instances, notably tsutsugamushi disease, Proteus agglutination suffices; in general, complement-fixation carried out with purified rickettsial antigen is the serological method of choice, and rickettsial agglutination is equally specific.

In epidemic typhus fever, the complementfixing antibody titer shows an eight-fold rise in titer against the specific antigen between the first and third weeks, and is usually fourfold or greater than the titer observed to R. typhi antigen in unimmunized persons. Similarly, in murine typhus the specific complement-fixing antibody titer rises from less than 1:10 in the first week to 1:60 or more by the third week and is consistently higher than titers to R. prowazeki antigen in unimmunized individuals. Rickettsial agglutinin titers of 1:200 are regarded as diagnostic in both diseases. It may be extremely difficult to distinguish between the two by serological reactions when the disease occurs in previously immunized persons.23

The complement-fixation titer rises about eight-fold from the first to the third weeks of the disease in spotted fevers, to a titer of 1:80 or higher. A similar complement-fixing antibody titer rise occurs in rickettsialpox, but a positive Weil-Felix reaction is given with the OX-19 or OX-2 strains of Proteus

in spotted fever, but not in rickettsialpox. An approximately similar rise in complement-fixing antibody titer to *C. burnetii* occurs in Q fever, usually without confusing cross-reactions.

Chapter Thirty-six

THE PSITTACOSIS— LYMPHOGRANULOMA VENEREUM GROUP OF MICROORGANISMS

The microorganisms making up the psittacosis-lymphogranuloma venereum group4, 69, 70 resemble one another closely, and it is believed that they may have differentiated from a common ancestral form by association with different host species. The group includes the causative agents of psittacosis and ornithosis, mouse pneumonitis, feline pneumonitis, human pneumonitis; organisms such as the Louisiana and San Francisco strains found in primary atypical pneumonia; the organism of opossum meningopneumonitis; and those causing bovine encephalitis and ewe abortion. The trachoma and inclusion conjunctivitis organisms are somewhat set apart from the group, although related to it, and are considered with it; the entire group is casually referred to as the PLT group of organisms.

The organisms of this group resemble the rickettsiae in a number of respects, i.e., they stain similarly and are sufficiently large that they fall just within the limits of optical resolution; there is some evidence that multiplication may include a process resembling binary fission; the diseases they produce may be treated effectively with certain antibiotics, and some strains are susceptible to the activity of sulfonamides. Similarities such as these have prompted some workers to group these microorganisms with the rickettsiae, but they are more appropriately regarded as another group of intermediate forms which constitute a link between the bacteria and the viruses. 55, 56 They are formally classified with the bacteria as members of the genus Chlamydia.59

These microorganisms occur in a variety of vertebrate hosts. Naturally occurring infections with the agents of lymphogranuloma venereum, trachoma, and inclusion conjunctivitis appear to be confined to man. Psittacosis occurs in psittacine birds, and the closely related, if not substantially identical, ornithosis occurs in wild birds such as pigeons and gulls, and in domestic fowl, especially the turkey; human infection is most commonly acquired by contact with such reservoirs of infection. Whether the pneumonitis agents of human origin, having minor but distinctive immunological character, occur primarily in man is uncertain. Pneumonitis infections in lower animals are relatively common; the infections are often latent, and it has been suggested that intensive study of apparently normal mice, birds, etc., may show the frequent presence of microorganisms of this kind.

Morphology and staining. The mature particle, or elementary body, is spherical or coccoidal in shape and relatively large, 200 to 300 m μ in diameter. The particle appears to consist of a central mass of electron-dense material surrounded by less dense material and enclosed within a limiting membrane. The structure is apparently not markedly rigid and tends to collapse on drying to give the appearance of a particle as much as 500 m μ in diameter. In shadowcast preparations the more rigid central mass is clearly apparent within the flattened particle. The membrane has been isolated and purified by lysis with desoxycholate and tryptic digestion, and found to resemble closely the cell walls of the gram-negative bacteria and rickettsiae in composition and properties⁴³ (Chap. Three).

Chemical analysis of purified elementary bodies of some of these microorganisms has shown that, like certain large viruses such as the poxviruses, they contain protein, lipid, carbohydrate, and both pentose and deoxypentose nucleic acids in proportions similar to those found in bacteria and rickett-siae.⁵⁴

Developmental cycle. These microorganisms occur in infected tissue as intracytoplasmic inclusion bodies or vesicles, and the morphology of these and the corpuscular elements making them up is variable as a consequence of the sequential occurrence of morphological types during the growth cycle as described elsewhere (Chap. Seven). In brief, following penetration of the host cell, the elementary bodies increase in size, to as much as 800 m μ in diameter, to become initial bodies which increase in numbers to form clusters or plagues in a ground substance or matrix. The corpuscular elements increase in number and decrease in size, giving rise to a vesicle containing large numbers of elementary bodies. In living preparations the particles are at first immobile, but as the vesicle matures the matrix apparently breaks down and the elementary bodies show brownian movement. Subse-

Figure 257. Shadow-cast electron micrograph of feline pneumonitis agent. Note the collapse of the spherical particle in the dried preparation showing the dense central mass and the outer limiting membrane. × 30,000. (Moulder and Weiss.)

quently the vesicle disintegrates, liberating elementary bodies which may then initiate a new infection. This growth cycle is completed in 24 to 48 hours, the time required depending on the strain of microorganism and the host tissue. Substantially this kind of growth cycle has been observed to occur with the meningopneumonitis, 37 psittacosis, 46 and trachoma^{2, 9} organisms.

Staining. The elementary bodies resemble rickettsiae in that they stain more readily with aniline dyes than do viruses, staining red with the Macchiavello stain and dark purple with the Castaneda stain. The relatively immature inclusion body, containing dense ground substance, is colored blue. As it matures the matrix becomes less dense, the larger particles are stained blue, and the smaller elementary bodies red by Macchiavello stain against the pale blue background of the matrix.

Toxin.¹⁹ All of the strains of lymphogranuloma venereum, psittacosis and ornithosis, and pneumonitis organisms examined have been found to be toxic. The activity is labile and destroyed in a short time at 37° C. or by low concentrations of formaldehyde. It is closely associated with the elementary body and would appear to be an endotoxin rather than an exotoxin. The toxicity is demonstrable by inoculation of mice with heavily infected tissue, commonly yolk sac of the infected embryonated hen's egg, in dilutions of 1:40 or less. Following intravenous inoculation with 0.5 ml. volumes death occurs usually within 24 hours. Because the toxicity has not been separated from living infective microorganisms, two-phase death curves may be observed, i.e., deaths attributable to toxicity occurring within 24 to 30 hours and those from infection beginning at about 48 hours. The common feature at autopsy is liver damage and often necrosis, but damage to the lungs and kidneys may occur also. The toxicity is specifically neutralized by antiserum (see below) but not by chemotherapeutic drugs.

Strains may vary considerably in toxicity. In a group of 39 strains, 22 of mammalian and 17 of avian origin, 17 of the mammalian strains killed in a dilution of 1:10 or greater, including two human pneumonitis strains that killed in a dilution of 1:80, while five of the avian strains failed to kill within 24 hours in dilutions of 1:10 or greater.⁴⁷ There is reason to believe that such toxicity may

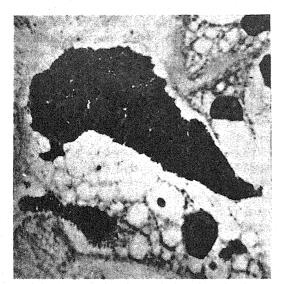

Figure 258. A mature intracellular vesicle of psittacosis in chick endodermal cell culture. May-Gruenwald-Giemsa stain; × 432. (Weiss.)

contribute significantly, as in the production of hemorrhage and edema in the lungs, to the pathogenesis of the diseases caused by these microorganisms.

Antigenicity. Complement-fixing. tective or neutralizing, and antitoxic antibodies are demonstrable. Two kinds of antigens, one heat-stable and one heatlabile, are concerned in complement fixation in the presence of convalescent or immune serums, and this reaction is useful for serodiagnostic purposes. Unfortunately, as usually carried out, it is nonspecific, not only with respect to microorganisms of the psittacosis-lymphogranuloma venereum group proper, but cross-reactions with these microorganisms are also given by the serums of persons infected with trachoma or inclusion conjunctivitis. With separation of the cell wall, it has been found that the group-specific complement-fixing antigens are intracellular, i.e., present in the lysate, while type-specific antigenicity occurs in the cell wall.44,62

The neutralization or protection test,¹⁸ carried out by incubation of the microorganism with antiserum prior to inoculation or previous passive immunization of the mouse respectively, was developed by Hilleman and by St. John and Gordon, and the toxin neutralization test by Manire and Meyer.⁴⁸ Only small amounts of protective and neutralizing antibody are found in con-

valescent serums so that such tests have no diagnostic utility. Hyperimmune serums from most laboratory animals are similarly deficient, but such antibody may be prepared to high titer in the rooster and used for differential purposes.³⁹

Both of these kinds of tests show a considerable degree of strain specificity. In a general way, infection experiments have suggested that the human pneumonitis strains are relatively specific, the strains of psittacine origin less so, and the meningopneumonitis (human) and pigeon strains have the broadest antigenic structures. More specificially, lymphogranuloma venereum, mouse pneumonitis, and feline pneumonitis agents have been found to be highly specific in the neutralization test, and, on the basis of antitoxic specificity. Manire and Meyer divided 27 strains into six groups, viz., (1) Louisiana (human) pneumonitis organisms, (2) San Francisco (human) pneumonitis organisms, (3) feline pneumonitis organisms, (4) meningopneumonitis (human) and certain ornithosis strains, (5) ornithosis strains isolated from pigeons, and (6) a group of strains of pigeon and human origin.

A hemagglutinin for mouse erythrocytes is formed by microorganisms of this group, allowing assay of hemagglutin-inhibiting activity.²⁴ It is not consistently present in infectious allantoic fluid, and is usually of low titer, 1:32 at the most, when present. It seems not to be eluted from mouse red cells, and the antigenicity appears to be nucleoprotein in nature and group-specific.²⁵

A passive hemagglutination test, using

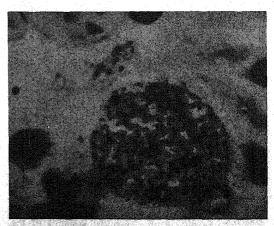

Figure 259. A vesicle containing elementary bodies from the lung of a mouse infected with mouse pneumonitis. Noble's stain; × 2100.

soluble antigen absorbed on tannic acidtreated sheep red cells, does not differentiate between ornithosis and pneumonitis -i.e., it is group-specific—but the sensitizing antigen is not identical with the complement-fixing antigen.

It is apparent that both common and specific antigens are distributed among these microorganisms and that different antigens are concerned in these tests. At the same time, neither the details of an antigenic structure nor the implications of host species on the immunological character of these organisms have been precisely defined.

Experimental infections. Differences in the pathogenicity of these microorganisms are evident in both the host range of naturally occurring infections and in the relative susceptibility of various experimental animals to infection. With the exception of trachoma and inclusion conjunctivitis agents, the mouse may be infected with all of the microorganisms of this group, and they may be grown in the embryonated hen's egg and various kinds of tissue culture.

Mice may be infected by the intranasal, intraperitoneal, and intracerebral routes to produce fatal infections with most strains of these organisms. Intranasal inoculation results in the development of a pneumonic process characterized by consolidation, and elementary bodies are found in large numbers in impression smears of the affected tissue. At autopsy animals infected by the intraperitoneal route show enlargement of liver and spleen and the presence of fibrous exudate in the abdominal cavity containing large numbers of elementary bodies. A meningoencephalitis with an exudate containing polymorphonuclear and mononuclear

cells is produced by intracerebral inoculation. Mice may also be infected by subcutaneous inoculation to give a generalized infection which is less often fatal and usually protracted.

These microorganisms may be grown in the embryonated hen's egg in the volk sac, where they multiply to high titer, and some grow well in the allantoic cavity or upon the chorioallantoic membrane. Multiplication of the feline pneumonitis agent in the yolk sac is associated with a high metabolic rate and an increased rate of synthesis of nucleic acid. According to Moulder and his colleagues⁵³ the energy for replication is supplied by high-energy phosphate bonds produced by the aerobic oxidation of endogenous substrates. Studies on the growth of psittacosis in chick embryo tissue culture^{3, 40, 50, 51} have shown that replication is dependent upon the presence of folic and/or folinic acid together with certain purines and amino acids. Although cytochrome C reductase activity1 and significant amounts of folic acid16 have been found in purified preparations of meningopneumonitis agents and in feline pneumonitis, mouse pneumonitis, and psittacosis agents, there is as yet no definite evidence that these microorganisms have a capacity for even the limited metabolic reactions demonstrable in rickettsiae.

Chemotherapy. 41 In general, tetracyclines effectively suppress the growth of these microorganisms, penicillin has an appreciable but lesser effect, and chloramphenicol and streptomycin are least effective. There is some variation among strains, and the San Francisco and Louisiana strains, and single strains of ornithosis agents of pigeon origin and of meningopneumonitis and feline pneu-

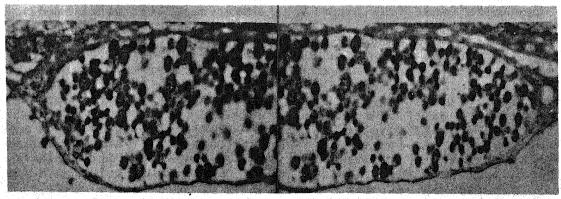

Figure 260. Electron micrograph of mature feline pneumonitis elementary bodies showing the two types of particles, the one smaller and dense and the other larger and granular in structure. × 15,000. (Litwin.)

monitis agents have been found to be unaffected by sulfadiazine.²⁹

The activity of these substances on these microorganisms is similar to their activity on sensitive bacteria, *i.e.*, they are primarily growth inhibitory. In the case of sulfonamides the activity is antagonized by paminobenzoic acid. Inhibition by penicillin and the tetracyclines is reflected morphologically as an abnormal growth; in the first instance irregular, vacuolated plaques are formed within the infected cell, and in the second multiplication of the initial bodies is inhibited.²⁶

Treatment of infections with these agents may result in an immune carrier state. The treated individual continues to harbor, or shed, the organism, sometimes for long periods, for example, in one human case of psittacosis for as long as eight years.

The growth-inhibitory effect of chemo-

therapeutic substances on the microorganisms of this group has been taken by some to imply the existence of as yet undetected independent metabolic activity. While this inference may eventually be substantiated by direct, and therefore more convincing, evidence, it is also possible that the effect is, as least in part, one upon the physiological mechanisms of the host cell concerned with replication.

Drug resistance. It is of particular interest that a number of these microorganisms may be made resistant to chemotherapeutic agents by passage in the embryonated egg or mouse in their presence. 27, 57 Such changes are presumably of the same nature as those observed with other microorganisms, and drug resistance has been used as a marker in genetic studies. 28, 58

Psittacosis and Ornithosis 49

Psittacosis, or parrot fever, was observed in Switzerland in 1880. For many years it was regarded as an unimportant disease, possibly caused by Nocard's bacillus, which is now designated Salmonella typhimurium. In 1929 and 1930 it appeared in many parts of the world as a disease acquired for the most part from South American parrots. The elementary bodies were described in 1930 independently by Levinthal in Germany, Coles in England, and Lillie in the United States, and for this reason are sometimes known as LCL bodies. Their nature and etiological relation to the disease were established in the early 1930's largely through the work of Bedson and his colleagues.

During that decade it also became apparent that exotic imported psittacine birds are not the only source of infection, and, in fact, that a domestic reservoir of infection occurs in gulls and other sea birds, pigeons, ducks, chickens, etc. The 1938 epidemic of pneumonitis in the Faroe Islands, for example, was associated with widespread infection in fulmar petrels. In the 1940's a variety of similar microorganisms was isolated from other lower animals and from human cases of pneumonitis.

The disease in man was originally called psittacosis because it appeared to be acquired largely from psittacine birds, and

the term ornithosis was introduced when the broader base of the reservoir of infection became apparent. The more inclusive term ornithosis, while not yet universally used, has gained increasing acceptance, especially for disease in, and acquired from, other than psittacine birds.

Pathogenicity for man. The disease produced in man by these microorganisms is essentially the same regardless of the source of infection. The incubation period is one to two weeks, and the onset may be sudden or insidious. The symptoms include chills and fever, photophobia, headache, anorexia, sore throat, nausea, and vomiting. A dry cough develops which persists and may become more severe, cyanosis and low blood presare frequent, and disorientation, apathy, insomnia, and occasionally delirium indicate involvement of the central nervous system. Leucocytosis does not occur until late in the disease or early convalescence, and the extent of the lung involvement is usually not apparent except by x-ray examination, which shows patchy areas of consolidation in one or both lungs. The organism may be found in the blood during the first week of the disease, and in the scanty sputum after the lungs are involved.

At autopsy the areas of consolidation are sharply demarcated from normal tissue;

alveoli containing air, serum, or serofibrous exudate, in which the cellular response is predominantly mononuclear, are dispersed in the areas of consolidation. The exudate cells and those of the hilar lymph nodes contain intracytoplasmic elementary bodies. Other necropsy findings include congestion and focal necrosis in the liver, possible enlargement of the spleen, cloudy swelling in the cardiac muscle, degenerative changes in the kidney parenchyma, and often congestion and edema of the brain and cord. Such findings are clearly indicative of the generalized nature of the infection. The case fatality rate was about 20 per cent in 1929 and 1930, dropped to about 10 per cent with the recognition of mild cases by serodiagnostic methods, and may be further reduced by therapy with tetracyclines.

Pathogencity for lower animals. Naturally acquired infection is not uncommon among certain lower animals and may occur, as a latent infection, even more frequently than has been supposed.

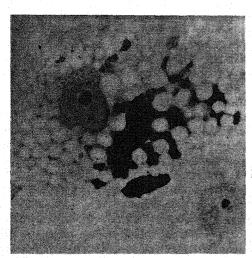

Birds. The natural hosts of these microorganisms among birds include parrots, parakeets, budgereegahs, etc., totaling not less than 31 species of the parrot family. Other birds such as canaries, finches, and sparrows contract the disease when exposed to infected psittacine birds; naturally occurring latent infection among pigeons appears to be relatively common, and microorganisms of the same group are found in doves, petrels, gulls, and egrets. The domestic chicken is naturally infected,

though not commonly, and spontaneous infection, possibly derived from wild birds such as gulls, and at times assuming epidemic form, occurs in turkeys. There are some differences in virulence and/or susceptibility, depending upon the strain of the organism and the host species. For example, strains of psittacine origin rarely produce fatal meningoencephalitis in pigeons, but those from pigeons and chickens usually produce fatal encephalitis on intracerebral inoculation.

In the parrot the disease is characterized by shivering, weakness, apathy and diarrhea, and respiratory disturbance may be evident. In these birds the disease is an infection of the liver and spleen with occasional involvement of the lungs, and the agent is present in the blood, affected tissues, nasal secretions, and feces. At autopsy of birds dying in the acute stage of the disease the spleen is enlarged and may show areas of focal necrosis, and the liver shows similar changes together with local hemorrhage and infarction, and a semipurulent exudate is found in the pericardial sac and on the air sac and inner lining of the sternum.

Naturally occurring infection in birds is frequently nonfatal, and there is reason to believe that there is a reservoir of latent infection of considerable proportions. Infected birds excrete the infectious agent in the droppings, and dried fecal material is an important source of airborne infection.

Mammals. A number of mammals are infected with closely similar microorganisms

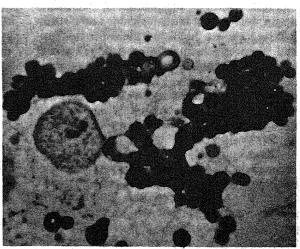

Figure 261. The effect of penicillin on the morphology of the feline pneumonitis organism. Left, untreated culture; right, penicillin-treated. The abnormal morphology in the presence of the drug is apparent, × 600. (Weiss.)

in a latent form, and such infections may be activated to give a clinically apparent, and possibly fatal, disease. This is a point of considerable practical importance in the isolation and study of organisms of this group. The meningopneumonitis organism, for example, which has been used extensively for experimental purposes, was originally isolated from ferrets inoculated intranasally with material from human pneumonitis; it is not clear whether the agent was present in the human disease and so isolated or whether it represented a latent infection in the ferret activated by the inoculation. Similarly, a number of these microorganisms have been found to occur as latent infections in mice.

Still other organisms of this group have been isolated from respiratory disease in man going under the names of virus pneumonia, pneumonitis, and primary atypical pneumonia. The majority of infections of this kind are of Mycoplasma etiology (Chap. Twentyseven) and are distinguished by the appearance of cold agglutinins in the serum, but some portion are of *R. burnetii*, miscellaneous viral, and other etiology.

Other mammals are naturally infected with microorganisms of this group, producing pneumonia of swine, meningopneumonitis of opossums, bovine encephalitis, ewe abortion, and cat distemper. The last, feline pneumonitis, has been widely used for experimental purposes. Of the usual experimental animals, the mouse is susceptible to infection with the organisms of this group by various routes of inoculation, the guinea pig gives little more than a febrile reaction to microorganisms of psittacine origin, but certain human strains and a strain from egrets are highly virulent for this animal. Some psittacine strains produce a fatal meningoencephalitis in the rabbit on intracerebral inoculation; rhesus monkeys may be infected by the intranasal or intracerebral routes, but rats are relatively resistant to intraperitoneal inoculation. In general, irregular results are obtained with the more resistant animals.

Immunity. As indicated above, the immune response results in the appearance of complement-fixing, protective, and antitoxic activity, varying with the host species. Complement-fixing antibody appears in 10 days to two weeks and hypersensitivity a week or two later. Effective immunity appears to be in part an infection immunity and dependent

upon the continued presence of the infectious agent. Some attempts have been made to produce a prophylactic immunity in man by the use of vaccines, but with as yet somewhat uncertain results.

Serodiagnosis. Serodiagnosis is dependent in practice on the complement-fixation reaction, carried out with paired serums to demonstrate a rise in titer. The rise occurs in 10 days to two weeks but may be delayed until two to five weeks by chemotherapy; a titer of 1:16, coupled with typical clinical findings, is often considered as positive.

The complement-fixation reaction is dependent upon one or the other of the complement-fixing antigens noted above. The heat-labile antigen is presumably protein in nature since it is inactivated by proteolytic digestion and tends to be strain-specific. and the heat-stable antigen, which is groupspecific, is considered to be polysaccharide because it is sensitive to periodate. The specificity of the test may be increased by preliminary absorption of the serum with steamed antigen and using living antigen in the complement-fixation test, but the use of living virulent antigen is impractical for routine purposes. Further differentiation between the two may be made on the basis of behavior of complement-fixing antibody titer; serums of persons infected with lymphogranuloma venereum organisms react to high titer with psittacosis antigen, but the titer declines during convalescence while that of psittacosis patients persists for many weeks or even months. As noted above, cold agglutinin is usually absent except in Mycoplasma infections.

The application of the complement-fixation to the diagnosis of avian infection is complicated in the case of chickens and ducks because immune serums from these birds do not fix complement in the presence of homologous antigen. A complement-fixation inhibition, or indirect complement-fixation, test, using heated antigen, has been devised⁴⁵ for use with such serums. In this reaction the fixation of complement by pigeon antibody in the presence of homologous antigen is specifically inhibited in the presence of antibody-containing serums of infected chickens or ducks.

Hypersensitivity. The hypersensitivity developed during infection has been useful for diagnostic purposes in surveys of flocks of domestic birds, especially turkeys. The antigen concerned is separable from com-

plement-fixing antigen by high-speed centrifugation, remaining in the supernatant. It may be extracted from infected yolk sac material with sodium lauryl sulfate, is precipitated by dilute acid, purified by butanol fractionation, differs from complement-fixing antigen in that it is soluble in 5 per cent phenol, and appears to be a lipocarbohydrate. Its activity is standardized in the guinea pig, and, inoculated intradermally into the wattles of turkeys, it gives the usual delayed type of hypersensitivity reaction which correlates well with the results of the complement-fixation reaction. 6

Laboratory diagnosis. Infection with these microorganisms may be established by isolation of the infectious agent from blood, sputum, or lung tissue taken at autopsy. The specimen is inoculated intranasally, intracerebrally, or intraperitoneally into mice and into the yolk sac of the embryonated egg. The microorganism is found as basophilic inclusion bodies and may be identified by serological methods.

Epidemiology. In the human disease the infectious agent usually enters the body via the respiratory tract. As indicated earlier, it is most often acquired from an animal reservoir of infection, usually indirectly by

inhalation of dried infectious material such as feces, and less commonly by direct contact with infected animals. Psittacine birds are the best known of these reservoirs, and infection appears to be common among wild parrots and parakeets, may assume clinical form in caged birds, and is generally endemic in aviaries and in breeding colonies of pigeons and ducks. The relative importance of mammalian, such as rodent, reservoirs of infection to the human disease is uncertain. Under some circumstances the infection may be transmitted directly from man to man as shown by a number of well-documented instances of infection of hospital or nursing personnel by patients. The highly contagious nature of the disease is evident from the number of laboratory infections which have occurred.

The incidence of the disease is largely an expression of risk. This factor accounts for its predominance in older women, and its tendency to occur as an occupational disease among professional handlers and breeders of birds. Control of the reservoir of infection in psittacine birds by quarantine has had some small success but in general depends upon avoiding sufficiently intimate contact with the animal reservoirs of endemic infection.

Lymphogranuloma Venereum

Lymphogranuloma venereum is a venereal disease caused by a microorganism closely related to the psittacosis-ornithosispneumonitis organisms described above. It is also known as climatic bubo, tropical bubo, lymphopathia venereum, and lymphogranuloma inguinale. The last is not to be confused with granuloma inguinale caused by Donovania granulomatis and discussed elsewhere (Chap. Twenty-seven). It was described as a clinical entity in 1913 by Durand, Nicolas, and Favre and is sometimes known as maladie de Nicolas et Favre. but it was not until the 1930's that its microbial etiology was recognized and the application of immunological methods allowed the grouping of various genital diseases such as elephantiasis of the female pudenda and inflammatory rectal strictures into a disease of common etiology.

The disease tends to occur in tropical regions, because of socioeconomic rather than climatic conditions, but its true in-

cidence is not known with any certainty because it is usually not reportable. In this country there appears to be a large reservoir of infection in the Negro as indicated by positive serological reactions in 25 to 40 per cent of those examined in certain areas.

The microorganism is morphologically indistinguishable from the others of this group and undergoes a closely similar, if not identical, growth cycle in the host cell. It is closely related immunologically through group antigens but is distinct in its pathogenicity, occurring apparently only in man as the natural host. While mice, monkeys, and embryonated eggs may be infected experimentally, this virus does not infect birds.

Pathogenicity for man.⁶³ Following the initial wide dissemination of the microorganism in the blood, spinal fluid, and other tissues, the primary lesion appears within a few days. It takes the form of a vesicular or herpetiform lesion occurring on the glans or prepuce of the penis, or on the posterior

portions of the labia, vaginal wall, or cervix, and may also be found within the urethra and in the anal region. The vesicle breaks down to leave a shallow ulcer that is not indurated and heals without scarring. This lesion is painless and is frequently overlooked.

The second stage of the disease is an invasion of the lymphatics. The regional nodes, commonly inguinal and also pelvic in the female, become enlarged and painful to form the bubo. In half or more of cases these suppurate, resembling similar lesions found in tuberculosis and syphilis, and may continue to drain for a long time. In this stage general as well as local symptoms occur, including fever and general aches, and in some cases arthritic and conjunctival symptoms and signs of involvement of the central nervous system may occur.

The third stage is an urethrogenitoperineal syndrome. The structural changes include nondestructive elephantiasis of the labia and clitoris in the female (esthiomene) and of the penis and scrotum in the male, and the rectum and anus become involved with the development of rectal stenosis, stricture, etc. The disease may be successfully treated with sulfonamides and the tetracyclines.³⁴

Pathogenicity for lower animals. The microorganism grows well in the yolk sac of the embryonated hen's egg. In mice inoculated intracerebrally leptomeningitis is produced, and the animals show incoordination, weakness, and paresis with a fatality

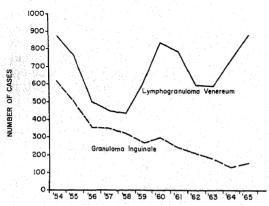

Figure 262. The incidence of lymphogranuloma venereum in the United States during the period 1954–1965 as indicated by the number of civilian cases reported. (Morbidity and Mortality Weekly Report, Annual Supplement, Vol. 14, No. 53. Communicable Disease Center, Public Health Service, U.S. Department of Health, Education and Welfare.)

rate of perhaps 30 per cent. On intranasal inoculation, pneumonitis, often fatal within a week, takes the form of a desquamative alveolitis with nodular inflammation around the capillaries and lymphatics, and the organism is demonstrable microscopically in the affected tissues.

The human disease is reasonably well reproduced in the monkey when inoculated into the prepuce, lymph nodes, or rectal tissue, with the development of typical inflammatory reactions. The monkey may also be infected by the intraperitoneal, intraocular, and intranasal routes, but not by intravenous or intracerebral inoculation.

Immunity. Effective immunity to this disease appears to be an infection immunity associated with continued presence of the infectious agent. Experimental inoculation of an infected individual gives a reaction similar to the Frei test (see below) but does not lead to the appearance of the initial vesicular lesion or an inflammatory response in the regional lymphatics.

The immune response is evidenced by the appearance of complement-fixing antibody in two to four weeks and the development of a hypersensitivity to the microbial substance. Both are useful for diagnostic purposes. The complement-fixation reaction is positive with serums from individuals infected with other microorganisms of the group (psittacosis, etc.), but may be made more specific by preliminary adsorption of the serum with heterologous antigen, and syphilitic serums may be nonspecifically positive. It is often not possible to obtain serum early in the disease, but a titer of 1:32 in conjunction with typical clinical findings is regarded as diagnostic, and an increasing titer has greater value.

Hypersensitivity was observed by Frei in 1925, and is demonstrable as a typical delayed reaction following intradermal inoculation infectious material. It was, in fact, the application of this reaction, the Frei test, that led to the identification of apparently diverse genital diseases, which had been known for many years, as manifestations of infection with this microorganism. The hypersensitivity develops one to six weeks after infection and remains positive apparently for the life of the individual, but transitory negative reactions may occur during sulfonamide therapy. The original Frei antigen was a 1:5 dilution of pus from a bubo in saline sterilized by heating. Mouse

brain antigens have not been satisfactory because of nonspecific reactions, and antigen prepared from the yolk sac of the infected egg is generally used. The skin test antigen is marketed under the name Lygranum. Cross-reactions³⁸ occur, but an acid extract of the microorganism appears to be more specific.

Epidemiology. The disease occurs all over the world¹⁷ and is found largely in ignorant persons of low economic status. It is usually, though not necessarily, trans-

mitted by sexual intercourse. Infection of the eye with an oculoglandular syndrome is known, and primary infection may occur in the mouth with painless vesicular lesions and swelling of the tongue, followed by infection of the glands of the neck. Occasional accidental infections occur, as in hospital orderlies infected while cleaning patients and in surgeons infected during removal of infected lymph glands. Control of the disease is difficult because it is not ordinarily reportable.

Trachoma and Inclusion Conjunctivitis 11,42

Trachoma and inclusion conjunctivitis are similar diseases of the external eye which are caused by microorganisms related to those of the psittacosis-lymphogranuloma venereum group. This subgroup is sometimes referred to as the TRIC (trachoma-inclusion conjunctivitis) group of agents. Naturally occurring infections are found only in man, and the host-specificity is sharp in experimental infections, which are similar to, but generally milder than, those in man, and can be produced only in certain primates.

TRACHOMA^{61, 64, 68}

Trachoma is an ancient disease and is referred to in the earliest known writings. It occurs in the Mediterranean area, especially in North Africa and the Middle East, in Russia, and the Orient, and in this country is found among mountain people in Tennessee, Kentucky, and West Virginia and among Indians on reservations. Its incidence is greatest, to as much as 90 per cent, in Egypt and the Middle East.¹⁰

There has been evidence of the microbial etiology of trachoma, and inclusion blennorrhea, since the work of the Trachoma Commission in the early 1930's. The reported isolation of trachoma agent in the embryonated egg by Tang et al.⁶⁵ in 1957 was subsequently confirmed by isolations in Africa,^{15, 66} in Taiwan, and in this country.³⁵ It may be isolated³⁰ and grown in cultures of human amnion cells, the McCoy cell line derived from human synovial tissue,⁶¹ and some strains may be adapted to HeLa cells,²²

as well as in the volk sac of the embryonated egg. It also produces a lethal pneumonic infection in mice following intranasal inoculation.32 In its morphology and other growth characteristics it resembles closely the other microorganisms of this group.³¹ It is related antigenically through group antigen but, when washed elementary bodies are used as complement-fixing antigen, the reaction is reported to be specific. 71 The elementary bodies contain a toxin, but it may not be antigenically homogeneous.⁵ The culture is susceptible to the broad-spectrum antibiotics⁶⁷ and reproduces the disease in various primates^{14, 20} with strain differences in virulence.

Pathogenicity for man. When the disease develops slowly, the first sign of infection is a slight ptosis of the lids, and there is a follicular hypertrophy of the upper tarsal conjunctiva. When the disease develops rapidly in a fulminating form, there is an inflammatory reaction characterized by a papillary or follicular hypertrophy of the conjunctiva and a mucopurulent exudate, and secondary bacterial infection is common, occurring in 50 per cent or more of cases. Intracytoplasmic inclusion bodies are found in the conjunctival and corneal epithelial cells in expressed follicular material and are most numerous in the cells from the superficial layers of epithelium from the upper tarsal and upper limbus areas.

The disease progresses with vascularization of the cornea and pannus formation and secondary cicatrization of the cornea, and partial or total blindness may result.

Microorganisms of this group also have been isolated from "nonspecific," i.e., non-

gonorrheal, urethritis.²¹ It may be successfully treated with sulfonamides or the broadspectrum antibotics.

There appears to be little or no effective immunity, since reinfection or relapse is not uncommon. Immunization with experimental vaccine, however, has been found to modify the experimental infection in human volunteers.³³ Infected individuals are negative to the Frei test but develop antibody which fixes complement in the presence of psittacosis and related antigens. The complement-fixation test is not sufficiently specific for diagnostic purposes; *i.e.*, it does not distinguish between trachoma and inclusion conjunctivitis.

INCLUSION CONJUNCTIVITIS

Inclusion conjunctivitis (inclusion blennorrhea, swimming pool conjunctivitis) is a benign conjunctivitis found in the newborn and in adults. It differs from trachoma in that pannus and scarring of the cornea are not observed; the disease is self-limiting and persistent chronic infection does not seem to occur although it may persist for some months, or even as long as a year in the adult.

The microorganism was isolated initially in the yolk sac of embryonated eggs by blind passage and eventual (ninth passage) adaptation to the egg,36 and subsequently elementary bodies were found at the first or second passage on primary isolation from the cervix of infected mothers and the eyes of infants.⁵² The culture produces a mucopurulent conjunctivitis in cynomolgus monkeys, and does not affect the cornea. It may be grown in cell culture¹³ and appears to be closely related in all respects to the trachoma agent. A preliminary study12 has suggested that an immunity effective under experimental conditions may be produced by vaccine.

Pathogenicity for man. In the newborn infant the incubation period is five to 12 days. The onset of the disease is sudden and characterized by an acute infiltration of the conjunctiva of the lower lid and a purulent exudate. The round cell infiltration results in a thickening of the conjunctiva, and the epithelium is infiltrated with polymorphonuclear cells and contains basophilic intracytoplasmic inclusion bodies indistinguishable from those of trachoma. The demonstration of these bodies, in epithelial

scrapings rather than exudate films taken for examination for bacteria, is diagnostic. Occasionally the disease is severe with the formation of transient pseudomembranes, but ordinarily it may be differentiated from gonorrheal ophthalmia on clinical grounds. The acute stage persists for perhaps two weeks and then gradually subsides, but the cornea does not return to normal for some months and may show evidence of infiltration for as long as a year.

The disease in the adult differs in that it is an acute follicular conjunctivitis with little discharge and a mild periauricular adenopathy. The follicles have the same appearance as those found in trachoma, but the hypertrophy is more marked in the lower lid, there is an absence of corneal change, and, on microscopic examination, the follicular material does not show necrotic changes. It may, however, be difficult to differentiate clinically from other forms of acute follicular conjunctivitis, and clinical diagnosis must be confirmed by the presence of inclusion bodies. The adult disease is also self-limited, resolving spontaneously without residual corneal or conjunctival changes, but tends to persist longer than in the infant.

Although overtly a disease of the eye, the infection is, in fact, one of the genitourinary tract and as such is transmitted venereally. Inclusion bodies are found in scrapings from the genitourinary tract of mothers of diseased infants, and the infection is apparently limited to the external os of the cervix and to transitional epithelium histologically closely similar to conjunctival epithelium. The infection is asymptomatic in the female but often produces a nonspecific urethritis in the male. Although of minor significance clinically, the genitourinary infection may be widespread.

The infant acquires the disease at birth from the infected mother, while the adult disease is most often acquired in swimming pools in which the water, which is not subjected to adequate chlorination or other treatment, is infected by persons having the genitourinary infection. Consistent with the nature of the reservoir of infection, inclusion conjunctivitis is an occupational disease of obstetricians and gynecologists. The serum of infected persons gives positive complement-fixation reactions with the group antigens and is not diagnostic for this disease. The disease in infants is not prevented by prophylactic silver nitrate, but

both the infant and adult diseases may be treated successfully with sulfonamides or tetracyclines, usually applied topically.

Chapter Thirty-seven

THE VIRUSES OF EXANTHEMATOUS DISEASE AND THE TUMOR VIRUSES

A number of viral diseases of man and of lower animals are exanthematous in nature, and the viruses causing them have been said to be dermotropic because the predominant lesions occur in the skin. 131 Certain of these make up the more or less homogeneous group of poxviruses, having in common the properties of relatively large size, often just within the limits of optical resolution, and a brick shape, and occurring as intracytoplasmic inclusion bodies in the infected cells. Others, however, are spheroidal in shape, range in size from somewhat below the limits of optical resolution to one of the smallest of the known viruses, that of footand-mouth disease, and infected cells may contain intracytoplasmic or intranuclear inclusion bodies. They are heterogeneous and, with minor exceptions, as varieties

of herpesvirus, do not fall into groups.

While infection of the host cell with a virus usually results in relatively rapid death, a number of these viruses induce a proliferative response which may be relatively brief and followed by necrotic changes or sufficiently prolonged that hyperplasia is an outstanding feature of the disease. The proliferative response is apparent, though transitory, in smallpox, is more pronounced in molluscum contagiosum in man and in fibroma in rabbits, and in rabbit papilloma and myxoma the process is so marked that the virus appears to have carcinogenic properties. The viruses which induce a pronounced proliferative response are sometimes grouped as the tumor viruses; such a group is heterogeneous; e.g., it includes both pox-like and smaller spheroid viruses.

The Pox Group of Viruses^{53, 58}

The viruses making up the pox group resemble one another morphologically and in the pathogenesis of the diseases they produce, and they are immunologically related to one another. They are differentiated by host specificity and relative pathogenicity. The group includes the virus of variola which occurs in man and that of vaccinia, together with the viruses causing a group of pox diseases of lower animals. The viruses of molluscum contagiosum and

of rabbit fibroma and myxoma are closely similar morphologically but tend to be set apart from the pox group on the basis of the diseases they produce. They are considered with the tumor viruses.

Morphology. The viruses of this group are among the largest of the viruses, and the elementary body is just within the limits of optical resolution. The higher resolution made possible by electron microscopy has made it clear that, at least in many prepara-

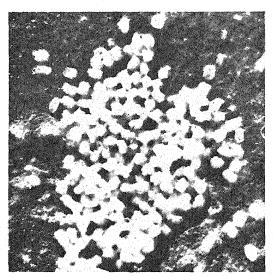

Figure 263. Electron micrograph of thin section through the chorioallantoic membrane of a 10-day chicken embryo 24 hours after inoculation with vaccinia. The numerous elementary bodies can be seen to possess a cuboidal or cylindrical shape. × 15,000. (Wyckoff: Zellforsch.)

tions suitable for examination by this method, the virus particle is a regular sixsided structure with rounded corners often described as brick-shaped, with dimensions of 200 to 250 m μ by 250 to 350 m μ . In some preparations the bodies appear to be ovoid in shape and in either case contain a central mass of electron-dense material.

These viruses occur as intracytoplasmic inclusion bodies known as Guarnieri bodies in the case of variola and vaccinia and as Bollinger bodies in fowlpox. These bodies differentiate into, and in mature form are composed of, elementary bodies called the Paschen bodies of variola and vaccinia and Borrel bodies of fowlpox. Both inclusion bodies and elementary bodies may be stained with polychrome stains such as Giemsa, by steaming with bicarbonate-crystal violet, and other methods, but do not stain satisfactorily with the usual bacterial stains.

Chemical composition. Like the rickettsiae and the psittacosis-lymphogranuloma venereum group of organisms, the chemical composition of the poxviruses is similar to that of bacteria, including nucleic acid in amounts of 6 to 7 per cent in contrast with the large amounts found in some other viruses, together with protein, polysaccharide, and lipid. The nucleic acid is DNA, predominantly double-stranded, and makes up the central core. Highly purified preparations have been found to contain copper and flavin together with biotin. If these are to be regarded as integral parts of the virus, they may represent rudimentary or vestigial fragments of a respiratory mechanism, but it is at least equally possible that such substances represent contamination originating in the infected tissue. The ether-resistance of the poxvirus group as a whole is variable, but the viruses considered here are ether-resistant.

Viral replication appears to Growth. occur in the cytoplasm of the infected cell. Following entry of the virus particle into the host cell, a portion of the cytoplasm surrounding it differentiates to form a matrix. When the matrix is dense it is the inclusion body, but viral replication may occur in a matrix that is not sufficiently dense to appear as an inclusion body. The matrix subsequently breaks down into elementary bodies, which may be in various developmental stages as described elsewhere (Chap. Four), and eventually the mass breaks down completely, and the cytoplasm of the cell is filled with elementary bodies which may then infect other cells.

Antigenicity. At least five kinds of antigens are present in the viruses of this group, certain of which are much better known in some of the viruses than in others. The LS soluble antigen of variola and vaccinia, found free in infected tissues, appears to be a single complex of which the L antigen is heat-labile and the S antigen is heat-stable. These antigens are demonstrable by complement fixation. A nucleoprotein (NP) antigen is present also, and these viruses form a hemagglutinin which agglutinates fowl erythrocytes, and in the case of mousepox mouse erythrocytes also, which is separable from the elementary body and associated with particles about 65 mu in diameter. The hemagglutinin activity is specifically inhibited in the presence of antibody.

During the replication cycle of the virus in HeLa cell culture these antigens appear in sequence. The LS antigen is detectable in about four hours, and the NP antigen in five to six hours, both in the cytoplasm of the infected cell and preceding the appearance of the infective particle. The hemagglutinating antigen is apparentely a by-product of virus-cell interaction and not found until about 10 hours postinfection.⁷²

None of the antibodies to these antigens

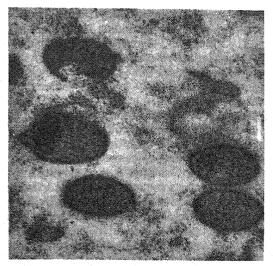

Figure 264. Electron micrograph of vaccinia virus in a section of infected chorioallantoic membrane showing the oval shape observed in some preparations. Note the small mass of electron-dense material in two of the virus particles. × 53,000. (Morgan: J. Exp. Med.)

is associated with neutralization or protection; rather, the ability to stimulate protective antibody formation is associated with infectivity of the virus strain, and it appears to involve antigens other than those just described.⁴

Pathogenesis of pox disease. 85 Although there is a considerable degree of host specificity among these viruses, differences in the pathogenesis of the diseases they produce may be considered to be variations on the same theme. The proliferative response alluded to above, for example, is minor in variola and vaccinia, but in some forms of fowlpox so marked that the disease has been known as contagious epithelioma.

The viruses may be grouped on the basis of tissue tropisms, e.g., the poxviruses are dermotropic, and such tropisms are inferred from the site of the overt or predominant lesion. It is significant, however, that viral replication may occur without obvious damage in cells and tissues apart from those in which the predominant lesions occur, and that such replication and dissemination may be an integral part of the pathogenesis of the disease. The occurrence of viremia, for example, exposes the virus to the action of humoral antibody and is fundamental to effective immunity to such a disease. In the case of mousepox the sequence of events has been worked out in detail by Fenner³⁵ (similar results have been obtained with rabbitpox¹²), and it is a fair presumption that this disease may be taken as a prototype, for the present at least, of similar pox diseases such as variola and vaccinia.

The incubation period of mousepox is about seven days, and by 11 days after infection the disease has progressed to severe rash with ulceration. Following initial infection, the virus multiplies in the skin and spreads to the regional lymphatics and multiplies there within the first two days of the incubation period. The virus is then shed into the blood stream to give primary viremia in the second or third day, spreading the infection to the spleen and liver, where it multiplies further and produces necrosis. Virus is again shed into the bloodstream to give secondary viremia on the fourth and fifth days, spreading the infection to the skin to set up foci of infection on the sixth day. By the seventh day, the end of the incubation period, the primary lesion, a swelling of the footpads, occurs; a papular

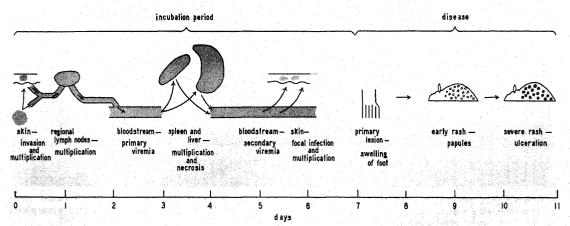

Figure 265. Diagrammatic representation of the pathogenesis of mousepox infection. (Redrawn from Fenner.)

rash appears by the ninth day which progresses to severe rash and ulceration by the eleventh day. This sequence of events is illustrated diagrammatically in the accompanying figure. Clearly, during the incubation period the virus is widely disseminated in the body, multiplying in cells not concerned in the primary lesion of the disease. As will appear (Chap. Thirty-nine), analogous phenomena occur in infections with other kinds of viruses also.

VARIOLA AND VACCINIA

Smallpox (variola) is an ancient disease which is known to have occurred in epidemic form in China as early as the twelfth century B.C., and is present in endemic, and from time to time epidemic, form in Asia, Africa, and the Middle East. It was widely disseminated in Europe during the Crusades, and was apparently introduced into the Western Hemisphere in the early sixteenth century, spreading into Central and South America, and new infection continued to be introduced by the slave trade.

This disease occurs in two forms differing markedly in severity. The one, variola major (malignant smallpox, black smallpox, etc.), is characterized by a case fatality rate of 25 to as much as 40 per cent. The milder form, variola minor, has a case fatality rate

of perhaps 1 per cent, and has been given a variety of names including alastrim, Kaffir pox, cottonpox, Cuban itch, and paravariola. The causative viruses of the two forms of the disease are almost indistinguishable except for a slightly greater virulence of variola major for the chick embryo. This difference in virulence may be enhanced by varying the temperature of incubation to give a laboratory test.²⁹ The diseases are differentiated on epidemiological grounds, *i.e.*, on the basis of the case fatality rate.

In many areas, including the United States, variola minor has tended to displace the malignant form of the disease. At the present time Asia and Africa are the main centers of variola major infection, with India the greatest single source of cases, and this form of the disease is endemic in Portugal in Europe and in Mexico in North America. 89 The introduction of variola major from endemic centers of infection remains a constant possibility; for example, this occurred in New York City in 1947. In this country the number of cases of smallpox has declined from the 30,000 to 50,000 cases reported per year in the 1920's to no confirmed cases being reported since 1954.

Vaccinia is almost always a purposefully acquired infection to produce immunity to smallpox (see below), and its occurrence in this way dates from Jenner's observations in the latter part of the eighteenth century.

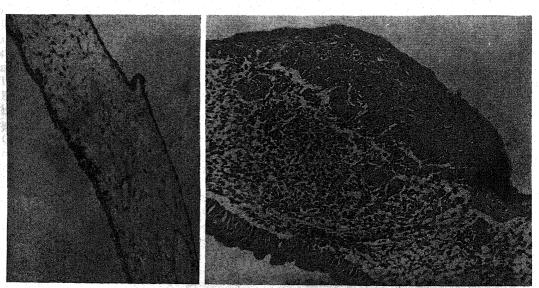

Figure 266. Sections of chorioallantoic membranes of 13-day embryonated eggs. *Left*, uninoculated; *right*, section through a variola lesion. Note the thickening of the membrane and discrete area of epithelial hyperplasia. × 100. (U.S. Army photograph, courtesy of Dr. N. Hahon.)

VARIOLA 863

Vaccinia is almost always a mild, localized disease in man; generalized vaccinia occurs rarely in the normal individual, but may occur when a nonimmune child with previously existing skin lesions, e.g., eczema, acquires vaccinia by contact.

Smallpox in man.²⁴ Variola virus is resistant to drying, and the crusts from pustules are highly infectious. Human infection is acquired by contact, direct or indirect. with such infectious material. There is reason to believe that in the typical disease primary infection occurs in the respiratory tract with multiplication of the virus in minimal, often but not necessarily noninfectious. lesions.28 The virus spreads to the regional lymphatics and into the blood stream to the viscera, where it multiplies during the latter part of the incubation period of about 12 days. When virus is released from these sites to give secondary viremia, symptoms, including chills, fever, prostration, headache, backache, and vomiting, appear, and the virus may be found in the blood. The secondary viremia gives rise to foci of infection in the skin, mucous membranes, and viscera, and the skin lesions appear. These occur as a single crop and are at first macular, and then pass through papular and vesicular stages to the pustule over a period of five to 10 days.

Histologically there is proliferation in the prickle-cell layer of the skin with the appearance of cytoplasmic inclusions. Intracellular edema, evidenced by the appearance of vacuoles, occurs and is followed by intercellular edema. The vacuoles enlarge, become confluent, the cell membrane is distended and breaks down, and vesicles are formed by the coalescence of adjacent affected cells. The epidermal reaction is followed by dilatation of blood and lymph vessels, involvement of the basilar layer, the appearance of an inflammatory exudate, and necrosis in the corium which leads to the typical scarring.

Chemotherapy. The most common complication is pyogenic infection, and antibiotic therapy is effective in minimizing such infection with consequent reduction in

N-methylisatin β-thiosemicarbazone

residual scarring, although chemotherapeutic agents are ineffective against the virus infection.

 β -thiosemicarbazone and some Isatin closely related compounds have been found to have antiviral activity in experimental poxvirus infections. This compound and the methyl derivative is effective against experimental variola, vaccinia, and cowpox as a prophylactic agent but inactive against mousepox, while the reverse holds true with isatin β -dialkylthiosemicarbazone.⁸ Nmethylisatin β -thiosemicarbazone has been tested in man and found to have marked prophylactic value in contacts.9 The nature of the antiviral effect is not understood, but it appears to be an interference with maturation of the virus particle.

Immunity. Smallpox has been the classical example of infectious disease in which recovery is associated with the development of a highly effective and long-lasting immunity, and there is no doubt that the individual remains immune for many years. The immune response is evident in the appearance, during the course of the disease, of complement-fixing and hemagglutinininhibiting antibody activity, but, as indicated earlier, these antibodies do not appear to be associated with effective immunity. Protective antibody is formed which, unlike complement-fixing and hemagglutinin-inhibiting antibodies that decline to insignificant levels in some 12 months, is demonstrable for years, and may be demonstrated by appropriate tests such as tissue culture assay.20

There is a high degree of cross-immunity among the various kinds of poxviruses which is demonstrable in experimental animals. That between variola and vaccinia is of a high order and allows the use of the latter mild infection to produce an effective prophylactic immunity to smallpox in man (see below).

Laboratory diagnosis. The laboratory diagnosis of smallpox assumes significance in the prompt and accurate identification of atypical cases in which the disease is modified by prior vaccination, and to exclude generalized vaccinia, varicella (see below), etc. It is dependent upon the demonstration of the presence of the virus, either directly or inferentially from the presence of specific antibody.

Inclusion bodies are found in stained smears from lesions in the papular and vesicular stages of the disease, and virus may be isolated from these lesions on the chorioallantoic membrane of the 12- to 14-day-old embryonated hen's egg. Specific antigen is demonstrable in the lesions by complement fixation in the presence of known antiserum.

The most readily applicable diagnostic tests are those for serum antibody, complement-fixing antibody, and hemagglutinininhibiting antibody. The former may not appear until the later eruptive stage of the disease. It has been reported that hemagglutinin-inhibiting antibody is detectable even in the pre-eruptive stage of the disease, reaching titers of 1:2000 by the end of the first week. Antibody titer is of questionable diagnostic significance in recently vaccinated persons, but a rising titer during the course of the disease may be regarded as diagnostic.

Vaccinia and immunization.^{13, 23} Antibody to the LS and NP antigens is produced by inoculation with noninfectious material, but it has not been possible to produce an effective immunity to smallpox by the use of inactive virus. The development of such an immunity appears to be dependent upon infection with variola or related viruses of which vaccinia is the most important.

The practice of variolation, deliberate inoculation of man by application of the dried crusts of variola pustules to the skin or nasal mucous membranes, or by ingestion, was common in the Orient in ancient times. It was introduced into Europe in 1718 by Lady Mary Wortley Montagu, wife of the British ambassador at Constantinople. The infection so produced was usually much less severe than naturally acquired smallpox, and the appreciable mortality rate considerably less than that of the natural disease.

Meanwhile it had been observed by a number of persons that those who contracted cowpox from infected cattle did not acquire smallpox upon subsequent exposure. Cowpox is an exceedingly mild disease in man, rarely if ever fatal, in which the lesion is almost always limited to the site of inoculation. These casual observations were extended by the Englishman Jenner, who published his classic treatise on the relation of the two diseases in 1796. Prophylaxis of smallpox by inoculation with cowpox, or so-called Jennerian prophylaxis, was favorably received and widely applied.

Vaccinia virus. It was assumed by Jenner that cowpox virus is variola virus adapted to the bovine host. The cow may be infected

with variola, at first with insignificant lesions following intracutaneous inoculation, but on passage in this animal a vesiculopustular eruption is produced which is similar to, but not identical with, that of naturally occurring cowpox. While variola, vaccinia, cowpox, and mousepox are closely related immunologically, antigenic differences may be distinguished by cross-neutralization tests. In this respect vaccinia is found to be more closely related to variola than to cowpox, and in turn cowpox is more closely related to mousepox than to variola.37 This suggests that present strains of vaccinia virus were derived from variola virus rather than cowpox virus, but it has not been possible to derive them experimentally.54 In this connection it is of interest that naturally acquired cowpox in man is a somewhat more severe disease than vaccinia, and that in recombination experiments with vaccinia variants in mixed infections in HeLa cell culture and on the chorioallantoic membrane, the recombinants, apparently analogous to bacterial recombinants, tended toward lesser virulence.38

Vaccinia in man. Human inoculation with vaccine lymph (see below) is usually intracutaneous by the so-called multiple pressure method in which 30 to 40 punctures into the skin are made with a needle through a drop of vaccinia virus preparation about 1 cm. in diameter. After three or four days a papule appears which becomes vesicular on the sixth or seventh day, progresses to a pustule at 10 or 12 days, and then regresses. Fever may occur from the fourth to eighth day, and there may be some tenderness and enlargement of the regional lymph nodes. The crust which forms on the pustule becomes detached about three weeks after inoculation (foveation), leaving a red pitted scar which turns white in time. Complications are quite rare. Generalized vaccinia, with eruption at other than the site of inoculation and a more pronounced general reaction, may occur when other skin lesions, such as eczema, are present at the time of inoculation. Postvaccinal encephalitis, which is extremely rare, is similar to that following the inoculation of other immunizing preparations.52

The foregoing reaction is that given by a fully susceptible individual and is sometimes called the primary reaction. It is modified in the partially or fully immune individual to give a vaccinoid reaction in the first in-

VACCINIA 865

stance and an immune reaction in the second. The vaccinoid reaction is similar to the primary reaction but accelerated and less severe. While there are gradations in the response, in general the papule appears at two days, and the maximum reaction is reached between three and seven days. The immune reaction consists of the development of a papule or shallow vesicle which reaches its maximum size in eight to 72 hours, disappears without going through a pustular stage, and leaves no scar.18 The immune reaction is given by inactivated as well as active virus and represents an allergic response to the vaccine material. It is of practical importance to emphasize that a vaccine giving the immune reaction is not necessarily active and therefore may not be an effective immunizing agent for the nonimmune.

Experimental Infections. Variola virus infects only man and monkeys but is readily cultivable on the chorioallantoic membrane of the embryonated hen's egg, where it produces pock-like lesions, and it may be maintained in serial passage in the yolk sac. The disease in monkeys⁴⁸ is similar to that in man, and there is some reason to believe that natural infection may occur. Only minimal lesions are produced in the rabbit and calf. It is extremely difficult to pass the infection serially in the rabbit, a characteristic that differentiates variola sharply from

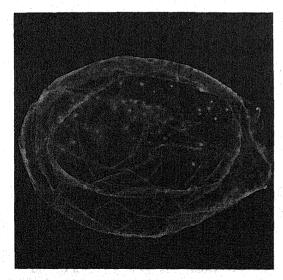

Figure 267. The gross appearance of the pock-like lesions produced by variola virus on the chorioallantoic membrane of the embryonated egg after 72 hours' incubation. Hematoxylin and eosin; × 100. (Hahon and Ratner, J. Bacteriol.)

vaccinia, and on serial passage in the calf the virus loses its original character and becomes vaccinia-like. The adult mouse may be infected by intracerebral inoculation but massive doses are required to produce regular death patterns. ¹⁴ The suckling mouse appears to be more susceptible and offers possibility for the assay of infectivity and protective antibody. ⁷⁷

In contrast, most laboratory animals may be infected with vaccinia virus, and it is readily cultivable on the chorioallantoic membrane of the embryonated egg, where it produces pocks closely similar to those of variola. The rabbit is the usual experimental animal, and infection is produced by all the customary routes of inoculation. The virus adapts relatively readily to growth on various kinds of tissues, and coincident alterations in virulence have resulted in strains which produce encephalitis, orchitis, or pneumonia, and strains differ in other respects such as pock morphology and heat resistance.

Vaccine for human use is usu-Vaccine. ally produced in the calf, though other animals, such as sheep, may be used also. The inoculum, or "seed" virus, is maintained at maximal activity by frequent passage in the rabbit and is used to inoculate the shaved abdomens of calves. After confluent vesicles have appeared along the scratches, the virus is harvested by scraping off the vesicle walls and contents, and this material, vaccine lymph, is emulsified in glycerol. The activity is stable for very long periods when vaccine lymph is stored at - 10° C., for about six months at 0° C., but for little more than a week at room temperature.

The virus may also be grown for vaccine purposes on the chorioallantoic membrane of the chick embryo, or in chick embryo tissue culture. Since the virus is grown under sterile conditions, problems of bacterial contamination, e.g., tetanus bacilli, etc., that are inherent in calf lymph vaccine production do not arise. These culture vaccines do not seem to be as effective immunizing agents as the calf lymph preparation, possibly because of adaptive changes to chicken tissue.

The activity of vaccines is assayed by the rabbit scarification test, 65 i.e., initial infection but not serial passage, but it has been urged by some that potency may be assayed equally, or possibly more, reliably by tissue culture methods 7, 19, 66 or by pock

counts on the chorioallantoic membrane of the embryonated egg.⁹⁶ Vaccine potency is referable to an international standard.⁶⁷

POX DISEASES OF LOWER ANIMALS

Pox disease occurs in a number of lower animals, including cattle, mice, and fowl, as noted earlier, and in addition in sheep, horses, swine, and a number of birds such as pigeons and canaries. In general, these diseases are characterized in the acute form by a vesicular eruption, but lesions may occur in the mouth as in stomatitis of horses, or the proliferative response to the infection may predominate as in one of the clinical types of fowlpox. In all of these diseases inclusion bodies of the Guarnieri type are found, often in large numbers, in the affected epithelial cells, and the causative viruses are morphologically closely similar and immunologically related to one another. Not all are equally well known, and only three, cowpox, mousepox, and fowlpox, will be considered here.

Cowpox. Cowpox is a mild, naturally occurring disease of cattle, characterized in the acute form by a vesicular eruption on the udder and teats. It is not a common disease, at least in the acute form. It is transmissible to man, as noted earlier in connection with Jenner's work, and the human disease is somewhat more severe than vaccinia. The virus is distinguished from variola and vaccinia in its hemorrhagic properties, apparent in the pocks formed on the chorioallantoic membrane of the chick embryo. and the vesicle fluid in bovine and human infections may contain blood. There is a cross-immunity between cowpox on the one hand and variola and vaccinia on the other, although minor antigenic differences are demonstrable. Cows may also acquire vaccinia from man.

Mousepox.³⁶ Mousepox, or ectromelia, is a naturally occurring infection of laboratory mice which was described as of viral etiology in 1930, and its relation to the pox diseases was demonstrated in 1945. It occurs in many parts of the world but does not seem to be present in this country as a naturally occurring infection, at least in the acute form. This disease has been particularly useful as a model experimental infection, such as for the study of the pathogenesis of pox disease, as described earlier, and as an immunizing infection comparable to

smallpox or diphtheria in experimental epidemiological studies (Chap. Ten).

The primary lesion develops at the portal of entry but is preceded by extensive multiplication of the virus and necrosis in the viscera, the spleen and liver particularly. In the acute form of the disease death occurs within two or three days after the appearance of the primary lesion, and on autopsy areas of necrosis are found in the liver and spleen. If the animal does not die at this point, a rash develops, at first papular and then vesicular with ulceration, and when the primary lesion is in the footpad, as is often the case, the tissue becomes edematous, then gangrenous, and sloughs off. The mortality rate is often high, but strains of the virus vary in this respect, and the infection may persist in latent form. The large cytoplasmic inclusion bodies are numerous in affected epithelial cells.

The virus produces only a latent, inapparent infection in the rat, it may be grown on the chorioallantoic membrane of the embryonated hen's egg, and rabbits and guinea pigs can be infected with egg-passage strains. It is immunologically related to variola and vaccinia and to cowpox.

Fowlpox. Fowlpox is a disease of domestic fowl which occurs in three clinical forms, *viz.*, the form in which the proliferative response results in the development of epithelioma-like growths on the comb, wattles, and skin of the head; the form in which yellowish membranous lesions are found in the mouth; and a form characterized by the presence of a watery or mucopurulent discharge from the nose and eyes known as roup.

The virus is morphologically similar to the other poxviruses, but somewhat larger than vaccinia and variola viruses. The virus particles, or elementary bodies, are known as Borrel bodies in this disease, and the large intracytoplasmic inclusion bodies are called Bollinger bodies. It is closely related to, but probably not identical with, the viruses of canary pox and pigeon pox. A variety of domestic birds may be infected experimentally, including the turkey, pigeon, goose, duck, and guinea fowl, together with a number of wild birds such as quail and pheasant. This virus, or closely related group of viruses, is set apart from the other poxviruses in that it is not pathogenic for mammals such as man, goat, sheep, mouse, rat, or guinea pig, but it is cultivable on the chorioallantoic membrane of the embryonated hen's egg.

The Herpesviruses

The group of agents considered to be herpesviruses characteristically proliferate in the nuclei of infected cells with the production of intranuclear acidophilic inclusion bodies. At one time the name Nitavirus (Nuclear Inclusion Type A) was suggested for this group, but has been discarded. The virus particle has cubic, icosahedral symmetry, the nucleocapsid is 95 to $105 \text{ m}\mu$ in diameter, and the particle is considerably larger, 180 to $250 \text{ m}\mu$, enclosed in its envelope. These viruses are ether-sensitive DNA viruses.

They fall into two subgroups, designated A and B:82 those of subgroup A are readily released from infected cells, while those of subgroup B are more closely cell-associated. Subgroup A includes the virus of herpes simplex (Herpesvirus hominis) occurring in man; that causing a naturally occurring disease of swine called pseudorabies or "mad itch;" a virus known as B virus found in monkeys which is immunologically related to both herpes and pseudorabies viruses; and virus III which occurs in rabbits. Subgroup B is made up of the varicella (chickenpox)-zoster virus found in man, and the cytomegaloviruses (salivary gland disease viruses), which occur in both man and lower animals.

HERPES SIMPLEX¹¹⁰

Herpes simplex (herpes febrilis, herpes labialis) is a naturally occurring disease of man characterized by vesicular lesions in the epithelial layers of ectodermal tssue and the presence of intranuclear inclusion bodies in the affected cells. The virus is a single entity with possibly minor variations in antigenic character between strains that do not seem to be reflected in the epidemiology of the disease. In the infected chorioallantoic membrane, the virus first appears as a small particle, 30 to 40 m μ in diameter, within the nucleus. These increase in size, apparently in part by the acquisition of a membrane, escape into the cytoplasm and acquire a second membrane, and finally emerge as mature particles.¹³² The presence of the virus in both nucleus and cytoplasm of infected cells has also been demonstrated by the fluorescent antibody technique.⁷⁰

In cell culture two general types of cytopathic effect are produced, (a) that characterized by the formation of syncytial giant cells, and (b) proliferative changes with the rounding and piling up of cells. These appear to be characteristics of strains which may be separated from one another when they become admixed. These varieties are substantially identical with respect to antigenicity and other biological properties but are reported to differ slightly in density as indicated by small differences in sedimentation rates. They are known as the GC, or giant cell, and P strains.

The disease in man. The vesicular lesions of herpes begin as a local burning sensation, followed by the appearance of papules which become vesicular and coalesce to form groups of thin-walled vesicles. The prickle-cell layer is affected with intra- and intercellular edema, and there is capillary dilatation and infiltration of inflammatory cells in the corium but no necrotic changes. The vesicular fluid contains epithelial cells and multinucleated giant cells with inclusions present in nuclei, and the fluid is infectious. The vesicles rupture, scabs are formed, and healing occurs without scarring.

Herpetic infection in man takes two forms regardless of the site of the vesicular lesions. The one is a primary infection, with severe, sometimes fatal, systemic effects, which occurs in individuals who do not show the presence of neutralizing serum antibody. The other, occurring in persons showing

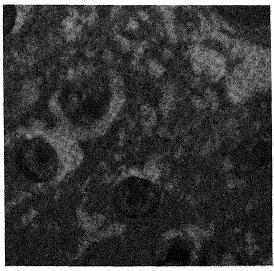

Figure 268. Intranuclear herpetic inclusion bodies in the human brain. (Armed Forces Institute of Pathology, No. 102644.)

neutralizing serum antibody, is characterized by the presence of local lesions but with minor or no systemic effects.

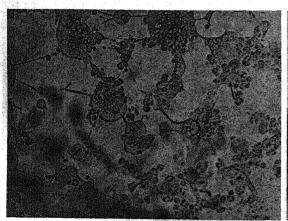

herpes. Primary infections Primary occur relatively early in life. Infants have an effective passive immunity, and infection seldom occurs in the first six months of life. By six years of age the proportion of individuals showing the presence of neutralizing antibody is increasing rapidly, and in adults the proportion of immunes is associated with economic status, 35 to 50 per cent at high levels and 90 per cent or more in lower income groups. The incidence of the primary type of infection is not sufficient to account for the high incidence of neutralizing antibody in adults, and it is probable that the primary infection is often subclinical; Scott has estimated that as much as 80 per cent of primary infections are subclinical.

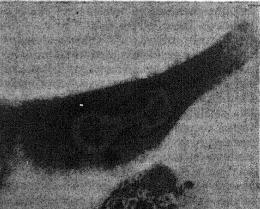

In the nonimmune the vesicular eruption commonly occurs in the mouth to give an acute herpetic gingivostomatitis (aphthous stomatitis, ulcerative stomatitis) in which the vesicular eruption appears as plaques and shallow ulcers; the tonsillar region may be affected, and the gums are often involved. This condition is to be differentiated from herpangina of Coxsackie virus etiology (Chap. Thirty-nine). The submaxillary lymphatics may become swollen and tender, and there is a constitutional reaction of varying severity, including high fever. Occasionally the virus invades the blood stream to give rise to a generalized vesicular eruption known as eczema herpeticum or Kaposi's varicelliform eruption which may simulate mild variola, generalized vaccinia, or severe varicella. The eye may be infected with the production of herpetic keratoconjunctivitis, or the central nervous system involved to give a herpetic meningoencephalitis. There is reason to believe that in the last instance the infection reaches the central nervous system via the peripheral nerves rather than by the hematogenous route. While primary herpes may be fatal, it is usually a self-limited infection, persisting for perhaps two weeks.

Recurrent herpes. Following primary infection, the virus persists in the tissues in spite of the presence of circulating antibody and constitutes an exception to the general rule that a solid immunity to viral infection is associated with the presence of neutralizing antibody. From the point of view of the virus, it is a highly successful parasite, persisting indefinitely in the tissues of the host.⁹⁴

This persistence in the presence of neutralizing antibody is apparently attributable to the spread of infection from cell to cell by direct extrusion. The cytoplasmic membranes of infected cells become altered so that they adhere to adjoining cells with passage of virus across the cell membranes, and in clumps of infected cells the membranes disintegrate to give rise to multinucleated giant cells which are found in the vesicles.¹⁰³

The infection is activated from time to time in various nonspecific ways, often some febrile reaction, so that herpes may

appear during convalescence from other diseases, physical shock such as chilling, metabolic or hormonal disturbances such as menstruation, etc. Under experimental conditions the infection may be activated by hypersensitivity reactions² or administration of adrenalin;¹⁰⁷ increased secretion of adrenalin occurs in many of the conditions in man associated with activation of herpetic infection. Individuals vary widely in their susceptibility to recurrent infection, *i.e.*, in the severity of the nonspecific stimulus required to induce an attack.

In recurrent herpes the disease is limited to a local vesicular lesion, presumably because of modification of the disease process by the pre-existing immunity. The eruption usually occurs at mucocutaneous junctures such as at the border of the lips or nares (fever blisters, cold sores). It may also occur on the genitalia *(herpes progenitalis) of either sex, on the glans penis or corona in the male and on the labia and lower vaginal mucous membrane in the female.

Chemotherapy. Herpes simplex may be treated effectively with certain halogen substituted uridines, especially 5-iodo-2'deoxyuridine (IDU), which is effective in both man and experimental animals by topical application. 49, 57, 60 The bromo derivative¹¹² and a methylamino derivative⁹⁰ have been found to be effective also under experimental conditions. Another analog, $1-\beta$ -Darabinofuranosylcytosine, has been shown to be effective in the treatment of experimental herpetic keratoconjunctivitis. 125 The discovery of such chemotherapeutic agents is of particular importance in the treatment of herpetic infections of the eye.

Immunity. As indicated above, recovery from primary herpes infection is associated with the appearance of neutralizing antibody in the serum which may be titrated in tissue culture.93, 108 It modifies subsequent recurrent disease but does not prevent it. Complement-fixing antibody appears concurrently, 109 and both antibodies reach peak titer in two to three weeks. The virus, at least that grown on the chorioallantoic membrane, contains two and possibly three kinds of antigens. One of these stimulates the production of neutralizing antibody and is separable by differential centrifugation from the soluble complement-fixing antigen, which also gives a skin reaction on intradermal inoculation into immune individuals. It has been reported that the soluble antigen

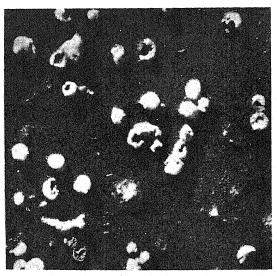

Figure 270. Herpesvirus elementary bodies in an ultrathin section of infected chorioallantoic membrane of the embryonated egg. Some particles are intact, while others show distortion produced by removal of the embedding agent (methacrylate) and the discontinuous structure of the particle. × 25,000. (Morgan: J. Exp. Med.)

is differentiable into a heat-stable and a heatlabile component, the latter giving the skin reaction but the evidence is not altogether consistent. The utility of the skin test has not been established.

Experimental infections. The virus may be grown on various kinds of tissue cultures, including rabbit testis tissue or kidney tissue, where it forms plaques; the occurrence of strains characterized by differences in cytopathic effect (see above) results in the macroplaque associated with syncytium formation, and the microplaque in which the host cells are rounded up. It may also be grown on the chorioallantoic membrane of the 12-day-old embryonated hen's egg, forming pock-like plaques on the membrane which differ from the larger, deeper necrotic pock produced by variola and vaccinia viruses; the typical lesion may not occur until the virus strain has been "egg-adapted" over two or three passages. The common laboratory animals, including the rabbit, mouse, hamster, and rat, may be infected by various routes of inoculation, the results depending somewhat upon the relative dermotropic or neurotropic tendencies of the virus strain. Inoculation of the rabbit cornea results in keratoconjunctivitis and corneal opacity, and this infection, together

established a

with that of the chorioallantoic membrane, is commonly used for diagnostic purposes. Intracerebral inoculation results in encephalitis, which may also occur in the rabbit following corneal inoculation with a neurotropic strain of the virus.

HERPETIC INFECTIONS OF LOWER ANIMALS

Among the variety of viral diseases of lower animals in which a vesicular eruption occurs, at least the three noted earlier are caused by viruses closely similar to the virus of herpes simplex. Although only one of these, B virus, infects man, they may be considered briefly here.

PSEUDORABIES

Pseudorabies (mad itch, infectious bulbar paralysis) is a naturally occurring disease of swine which is relatively mild but highly contagious in this animal. It occurs in Europe and the Americas, and in this country appears, on the basis of neutralizing antibody surveys, to be prevalent among pigs in the Middle West. In the acute form the onset is sudden after a very short incubation period, and the disease is characterized by intense pruritus and late paralysis, with sudden death after one to two days. The disease also affects cattle, horses, goats, sheep, dogs, cats, and other domestic animals, but not man. The common experimental animals, of which the rabbit is one of the most susceptible, are readily infected by any route.

The virus is widely distributed in the body and is present in saliva, but the disease is an acute infection of the central nervous system. It progresses so rapidly that gross signs are not marked other than hyperemia of the meninges and evidence of hemorrhage there and in the lungs. The virus apparently reaches the central nervous system via the peripheral nerves, producing degeneration of the nerve and glial cells in the spinal ganglia and in the corresponding segments of the cord in rabbits. In cattle the nerve and glial cell degeneration occurs in the cerebral cortex and is marked in Ammon's horn.

B VIRUS⁵¹

This virus was originally isolated (1934) from a fatal case of acute ascending myelitis in a laboratory worker who had been bitten by an apparently normal rhesus monkey. It was isolated subsequently directly from the monkey, and there is reason to believe that a benign infection is not uncommon in rhesus monkeys. Human infection is rare, but occurs in laboratory workers and others concerned with handling monkeys.73 The clinical disease is highly fatal, 13 fatalities occurred in 15 cases reported to 1966.95 Rabbits and guinea pigs may be infected experimentally, the virus showing strong neurotropic tendencies, and the virus may be grown on the chorioallantoic membrane of the chick embryo. The virus may be grown in various kinds of tissue cell culture; and variants, characterized by different kinds of cytopathic effects, have been described.34 Neurotropism is less marked in the monkey, and experimental infection produces a generalized infection with a vesicular rash.

The virus is closely similar to that of herpes simplex, being of about the same size and producing intranuclear inclusion bodies in affected cells. It is immunologically related to both herpes simplex virus and pseudorabies virus. Melnick and Banker⁸⁰ found neutralizing antibody in pooled human γ -globulin and in the serum of 11 of 40 persons examined in Bombay, as well as in nine of 44 apparently normal monkeys. It is supposed that the infection is endemic in monkeys, but interpretation of serological evidence, especially in man, must take into consideration the cross-reaction with herpes simplex virus.

VIRUS III

This virus was found in apparently normal rabbits by Rivers and Tillett in 1923 and again by Andrewes and his co-workers.³ The naturally-occurring infection is asymptomatic, but the presence of the virus in infected rabbits is demonstrable by serial intratesticular blind passage to eventually produce lesions in the testicles, skin, and cornea. Intracellular inclusion bodies, closely similar to those of herpes simplex, are found in the affected epithelial and endothelial cells. The virus can be grown in rabbit testis tissue culture, producing

typical intranuclear inclusions. So far as is known, it does not infect man or other animals.

VARICELLA AND ZOSTER

Varicella (chickenpox) and zoster (herpes zoster, shingles) are exanthematous diseases of man characterized by a vesicular eruption and the presence of acidophilic intranuclear inclusion bodies in the affected cells. Zoster, often known as herpes zoster, is quite unrelated to herpes simplex, but both this disease and chickenpox are caused by a virus of the herpes group.

The morphology of the virus particle is closely similar to that of the herpes simplex virus¹ as observed in vesicular fluid, and intranuclear inclusions are produced in cell culture. It is cultured with some difficulty in human cell cultures, amnion, lung fibroblasts with plaque formation, 99 and primary thyroid cell cultures. 15 Serial passage usually requires transfer of infected cells, but heavily infected thyroid cells have been reported to release infective virus into the medium. It has not been possible to infect experimental animals except, perhaps, the monkey.

Varicella. Chickenpox is a common, highly contagious exanthematous disease of childhood which occurs in epidemic form. After an incubation period of two, to

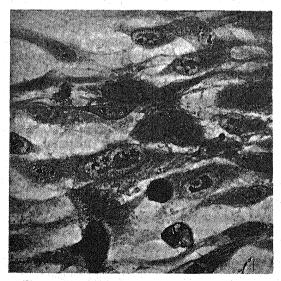

Figure 271. Varicella. Fifth culture passage in foreskin tissue of fluid from varicella lesion. Focus of cells with intranuclear inclusions on sixth day after inoculation. × 550. (Weller: Proc. Soc. Exp. Biol. Med.)

possibly three, weeks, there is a febrile reaction, and a macular eruption appears which progresses to the vesicular stage and may become pustular. These lesions occur in successive crops and may be observed in all stages of development. The prickle-cell layer is affected but without the reticular degeneration which occurs in variola. As the lesion develops, the intercellular edema becomes much more marked than in the variola vesicle, an inflammatory exudate appears, and giant multinucleate cells are present. The corium may form the base of large lesions with consequent scarring, but in general the necrotic changes found in variola lesions do not occur. The lesion is unilocular even at an early stage and can be distinguished from the early multilocular vesicle of variola-vaccinia infections. In the adult there is some tendency toward a varicella pneumonia, which may be less rare than commonly supposed. 68, 84

Some neurotropic tendency of the virus is evident in this disease by the occasional occurrence of encephalitis as a complication, and there may be neuritis of the cranial nerves. The disease is not affected by chemotherapeutic drugs, but chemotherapy is useful in minimizing secondary bacterial infection of the lesions.

Zoster. The vesicular eruption of zoster, or shingles, is substantially identical with that of varicella, but the disease is distinguished from varicella by its sporadic occurrence in adults, inflammation in spinal or extramedullary ganglia accompanied by severe pain localized to some portion of the involved nerve, and the tendency of the vesicular eruption to follow the distribution of one or more cutaneous sensory nerves, usually of the torso.

The disease is initiated by a febrile reaction, general malaise, and extreme tenderness along the dorsal nerve routes. A macular eruption appears within three to four days which becomes vesicular, and pustular when secondary bacterial infection occurs. The dorsal roots of the trunk are most often affected, but involvement of the maxillary or mandibular divisions of the trigeminal nerve may occur, with vesicular lesions in the tonsillar area or buccal mucosa; the ophthalmic division may be affected with scleritis and lesions of the cornea and conjunctiva; or involvement of the geniculate ganglion with corresponding vesicular lesions may occur. Meningoencephalitis is an uncommon complication, and persistent neuralgia tends to occur in older persons. It is clear that the neurotropic tendencies of the virus are much more marked in zoster than in varicella.

Relation of varicella and zoster. It has long been apparent that these diseases are intimately related. While varicella occurs largely in children and zoster in adults, contact with varicella possibly can result in zoster in adults, though convincing evidence is lacking, but zoster seems to have been the source of varicella, at times in epidemic form, in children. The virus particles found in vesicular fluid in the two diseases are morphologically indistinguishable, but evidence of antigenic relationship is inconclusive. Zoster may occur in children or adults who have recovered from varicella, and it is uncertain whether there is a cross-immunity between the two diseases. Some workers have reported substantially complete identity of complement-fixing antigen present in vesicular fluid, but this has not been observed by others. An immunological relation is, however, indicated by the agglutination of varicella virus particles in zoster convalescent serum, though to a lower titer than in homologous convalescent serum, and the fluorescent antibody technique has also shown the presence of common antigens in the two viruses.¹²⁸

It may be concluded, as a working hypothesis, that the two diseases are produced (a) by closely similar viruses, one tending to be dermotropic and the other neurotropic, or (b) by the same virus, some strains of which are sufficiently neurotropic that they are able to persist in the spinal ganglia following recovery from varicella, and the latent infection may be activated by massive doses of varicella virus or other nonspecific insult. 55 It has been suggested also that zoster represents varicella infection modified by a partial pre-existing immunity.

Cat-scratch Fever⁹⁷

Cat-scratch fever (nonbacterial regional lymphadenitis, benign inoculation lymphoreticulosis, cat-bite fever) is a disease of man, apparently acquired from cats, in which there is a primary papular lesion at the site of inoculation which may progress to a small ulcer, and, in a few instances, a transient localized measles-like eruption has occurred. There is a systemic febrile reaction in about two-thirds of the cases and anorexia, malaise, weakness, and aches; occasionally the central nervous system is involved, and there is a regional lymphadenopathy. The immediate regional nodes are inolved first, and subsequently secondary nodes may be affected. There is swelling and tenderness. and the nodes become indurated or suppurate and may require surgical drainage. The affected nodes are encapsulated and occur as three histological types, viz., the acute caseous type or soft tuberculoid granuloma, the acute necrotizing lesion containing a core of polymorphonuclear leucocytes and no definite demarcation from the surrounding tissue, and an epithelioid lesion which is a group of epithelioid cell granulomata with germinal center hyperplasia and no evidence of cellular degeneration.

The epidemiological character of the disease suggests that it is of an infectious etiology. Most cases have a history of skin

injury from a claw scratch or bite of cats, but there is no relation to an obvious illness of the animal. The apparent feline origin of the infectious agent, the nature of the disease in man, and the development of antibody fixing complement in the presence of antigens of the psittacosis-lymphogranuloma group of microorganisms, has suggested that the etiological agent may be a member of that group. But the occurrence of such antibody is irregular, in probably not more than 50 per cent of cases, and this and the failure to react to the Frei test makes such a supposition quite uncertain.⁵

The pus obtained from infected lymph nodes, prepared similarly to the original Frei antigen, has been found to give an apparently specific skin reaction in cases of the disease. 69, 100, 127 This material agglutinates rabbit erythrocytes, and hemagglutination is inhibited by patients' serum and by rabbit antiserum to the pus.²⁷ A hemagglutinating agent has been isolated and passed serially in the allantoic cavity of the embryonated hen's egg. 124 This agent has no cytopathic effect in cell cultures and produces no evidence of infection in the rabbit cornea, but its hemagglutinating activity is inhibited by antiserum to herpes simplex virus. CONTRACTOR OF THE STATE OF

Infectious Mononucleosis⁷¹

Infectious mononucleosis (glandular fever, monocytic angina) is an acute, presumably infectious, disease occurring in children and young adults characterized by an increased number of monocytes and large lymphocytes in the blood, angina, lymphadenitis, and the presence of heterophile antibody in the serum. It is known in Japan by a variety of names, including Tokushima fever and Kagami fever. A similar disease of lower animals in which the central nervous system may be involved with some frequency is caused by the bacterium Listeria (Chap. Twenty-seven), monocytogenes which also occurs as a natural infection of man. This microorganism is not found in the great majority of cases of human disease with the syndrome characterizing infectious mononucleosis. While there is no definitive supporting evidence, it is generally assumed as a working hypothesis that this disease is of viral etiology.

The disease in man.33 The onset of the disease may be acute or insidious and is characterized by loss of appetite and fatigue. Systemic involvement is indicated by the febrile reaction and symptoms such as epistaxis, nausea and vomiting, and headache; the cervical lymph nodes become swollen and tender, and there is angina ranging in severity from mild hyperemia to a pseudomembranous ulcerating form. A cutaneous rash occurs in some individuals, there may be conjunctivitis and/or evidence of liver damage, and the central nervous system is occasionally involved. The white blood cell count increases, to as much as 80,000, the differential count showing a decrease of polymorphonuclear leucocytes and a marked increase in monocytes to give a characteristic blood picture.

The serological evidence of infection is an

increased titer of heterophile antibody, demonstrable by agglutination of sheep erythrocytes (the Paul-Bunnell test) over the normal titer of 1:50 to 1:60; a titer of 1:80 is generally regarded as the minimum which may be taken as diagnostic. The hemagglutination test may be made more specific by a preliminary absorption of the serum with boiled guinea pig kidney tissue, which removes "nonspecific" antibody; the antibody associated with this disease is absorbed by treatment of the serum with boiled sheep erythrocytes. The goat erythrocyte is reported to give a more sensitive test, and a number of variations, including an ox erythrocyte hemolysis test and the use of trypsinized bovine red cells have been suggested.21

The disease is thought to be transmitted by intimate contact such as kissing, and it has in fact been called "kissing disease." It is not ordinarily possible to trace contact between infected persons; this has been interpreted by some to be indicative of a low degree of contagiousness and by others to suggest that subclinical infection is very common.

Experimental infections. Transmission of the infection, evidenced by mild lymphadenitis and small increases in the monocyte count, to the monkey has been reported by some workers but not by others. It has not been possible to cultivate an etiological agent in the embryonated egg, and human volunteer experiments have given equivocal results. More recently Japanese workers have produced a disease resembling mononucleosis in monkeys by parenteral, but not oral, inoculation with *Rickettsia sennetsu*, 111 an organism isolated in 1954 from persons ill with disease diagnosed on clinical grounds as infectious mononucleosis.

The Cytomegaloviruses¹¹⁶ (Salivary Gland Disease Viruses)

A disease known as salivary gland disease occurs widely in man¹¹⁷ and in a number of animal species examined, including rats, mice, guinea pigs, hamsters, Cebus monkeys, and chimpanzees. It is characterized by cellular gigantism and intranuclear inclusion bodies (and sometimes small compact intracytoplasmic inclusion bodies) present within the affected cells, whose size and

structure tend to set them off from the inclusion bodies observed in other viral diseases.⁷⁴ This disease, also known as cytomegalic inclusion disease, appears to be caused by a group of closely related, but highly species-specific, viruses.

The naturally occurring infection in lower animals seems to be almost invariably asymptomatic. It is probably usually sub-

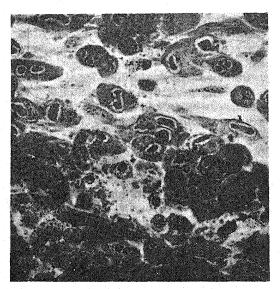

Figure 272. Salivary gland virus in human foreskin tissue culture showing the edge of a focal lesion, with central degeneration and infected cells at the periphery. Hematoxylin and eosin; × 360. (Weller: Proc. Soc. Exp. Biol. Med.)

clinical in man also, but severe disease occurs in infants,46 commonly in those under two years of age, and about 100 fatal cases have been reported in all; in older children it may be secondary to some other disease. The infection is generalized, and the typical histopathology is found at autopsy in the salivary, most often submaxillary, glands, in the kidneys, liver, lungs, pancreas, and occasionally in the brain. The virus is found in the saliva and urine. The infection persists for extended periods as indicated by isolation of virus from the urine for as long as four years, 129 and it is believed by some that, like herpes simplex virus, it may persist indefinitely.

The causative viruses have been isolated in salivary gland disease of the mouse, guinea pig, and man, in the last from salivary glands, kidneys, and adenoids, in tissue culture of homologous fibroblasts of varied tissue origin. 104, 115 After not less than 30, and up to 70, days of incubation, focal areas of degeneration appear on the fibroblast sheet which are separated by normal cells and which may become confluent on continued incubation. The cells in the affected areas contain the typical large acidophilic intranuclear inclusion bodies. While such cultures may be maintained in serial transplant, the virus grows only on homologous fibroblasts - i.e., mouse virus will not grow on human fibroblasts, or human virus on mouse fibroblasts - and cannot be grown on the usual HeLa cell, monkey kidney, or rabbit trachea tissue cultures. Active virus is present in the homologous fibroblast cultures: intraperitoneal inoculation young mice with cultured mouse virus produces a fatal disease characterized by visceral necrosis; and a fatal infection is produced by the intracerebral inoculation of fetal or very young guinea pigs with homologous culture virus, but human virus will not infect these animals.

The cytopathic effect in fibroblast culture is inhibited in the presence of antiserum, and antigen fixing complement in the presence of antiserum is present in tissue cultures. By such tests the human strains of the virus are shown to be immunologically distinct from varicella and measles viruses and show a degree of serological heterogeneity among themselves. They are morphologically indistinguishable from the other herpes viruses. 114, 134

The general occurrence of the disease in man is indicated by the incidence of typical histopathology in 10 to 30 per cent of infants at autopsy regardless of the immediate cause of death, the isolation of the virus from apparently normal adenoidal tissue, and the distribution of complement-fixing antibody. The observed incidence of significant titers of this antibody has been 14 per cent in the six- to 23 months age group, 53 per cent in the 18- to 25-year age group, and 81 per cent in persons over 35.133

Tumor Viruses 25, 44, 75, 78, 121

The property of some viruses of inducing proliferation of the affected cells has been alluded to earlier. In many instances proliferation is followed by necrosis, relatively rapidly in a disease such as smallpox in which the proliferative stage is so transitory

as to be almost inapparent, and more slowly in the epitheliomatous type of fowlpox infection. In infections with other viruses morphologically closely similar to the poxviruses, molluscum contagiosum in man and myxoma and fibroma in rabbits, the proliferative response predominates, but necrosis occurs eventually.

Still other viruses, notably that of rabbit papillomatosis, enter into a continuing, benign relationship with the host cell, and an orderly proliferation may continue for extended periods, but eventually the growth becomes disorderly, invades contiguous tissues, metastases occur, and the rapidly proliferating cells develop as a malignant process; i.e., the proliferative process has become cancerous. The mammary carcinoma of the mouse associated with the virus-like milk factor is similar in that the activity present in the milk produces no immediately apparent effect but is essential to the subsequent development of the carcinoma. In still other instances, such as avian sarcoma and leucosis, the proliferative response is malignant substantially from the initiation of the viral infection. Thus a continuous series of types of cellular proliferative response to viral infection may be constructed.

The relation of the virus to unrestricted proliferation is not clear, for evidence of its indefinite persistence in the affected tissues may be equivocal or lacking. In some instances the virus may not be directly separable from the affected tissues, but its continued presence and increase in amount are inferred from rising antibody titer to it in the blood, the infection persisting in masked form presumably because of the concurrent presence of antibody. In the case of avian leucosis virus prepared and studied in highly purified form by Beard, Sharp, and their colleagues, the viral agent, although extrinsic to the host cell and not arising de novo from it, nevertheless contains host tissue antigen as an integral portion of the viral substance, and the differentiation of virus and host cell tends to blur. In still other instances, the virus is detectable only in the earlier stages of the neoplastic process. and thereafter there is no evidence of its presence; under such circumstances the virus would appear to function, in current terminology, as a carcinogen, possibly by incorporation into the genome of the host cell.64

As yet it has not been possible to associate viruses with cancerous disease in man, 87, 101, 123 but a number of viruses are oncogenic in warm-blooded animals. These may be considered to fall into three groups:

(1) Poxviruses, including molluscum contagiosum and the fibroma-myxoma viruses

(2) Papovaviruses (papilloma-polyoma-vacuolating viruses) and some types (7, 12, 18, 31) of the adenoviruses (Chap. Thirty-eight)

(3) The avian leukosis, mouse leukemia, and mouse mammary cancer viruses. Of these, viruses of the first two groups are DNA viruses, and those of group 2 are 40 to 80 m μ in diameter, are ether-sensitive, have cubic symmetry, and are not enclosed in an envelope or limiting membrane. Those of the third group are RNA viruses approximately 100 m μ in diameter, of uncertain, possibly helical, symmetry, enclosed in an envelope, and ether-resistant. Clearly, the oncogenic viruses are heterogeneous by the usual criteria.

MOLLUSCUM CONTAGIOSUM

Molluscum contagiosum is an infectious disease of man, world-wide in distribution and occurring in both sporadic and epidemic form. The infection is spread by contact, and the disease is characterized by the occurrence of multiple nodules on the face, arms, back, and buttocks which are at first red, then pearly white, and undergo necrosis with the discharge of caseous material. The disease is chronic, and the lesions persist over several months.

The lesion develops in the epidermis as thickened areas of hyperplasia and hypertrophy of the affected cells. There is little or no reaction in the corium in the absence of secondary bacterial infection, and the pathological changes become more marked proceeding from the germinal layer to the surface of the epidermis. The affected cells are enlarged and practically filled with an acidophilic granular inclusion body, molluscum body, similar to those observed in the pox diseases.6, 17 The inclusion body contains oval or brick-shaped elementary bodies 230 by 330 m μ in size. In ultrathin sections the elementary bodies are heterogeneous with respect to contained electrondense material, and the several morphological types may be interpreted as representing a sequence of developmental stages as described elsewhere41,79 (Chap.

It has not been possible to infect experimental animals with this virus nor to grow it on the chorioallantoic membrane of the embryonated egg. Heat-labile soluble antigen may be prepared as extracts of macer-

ated infected tissue, which fixes complement in the presence of serum of some patients and has been shown to be unrelated to the antigens of the poxviruses.

MYXOMA AND FIBROMA VIRUSES

Infectious myxomatosis of rabbits is a naturally occurring mild disease of the South American rabbit (Sylvilagus braziliensis) and a rapidly fatal disease of the European wild rabbit (Oryctolagus cuniculus) and the common laboratory rabbit derived from it. The disease was described by Sanarelli in 1898 as occurring in laboratory rabbits in Montevideo. Infectious fibromatosis is a naturally occurring benign disease of wild cottontail (Sylvilagus species) rabbits, described by Shope in 1932, characterized by fibromata which eventually regress. The viruses causing these diseases are closely related immunologically, are morphologically indistinguishable, and are transmitted by arthropods, and the fibroma virus may be transformed to myxoma virus.

Infectious myxomatosis. While the virus of myxoma produces only benign tumor-like masses in Sylvilagus rabbits, the infection in Oryctolagus rabbits produces a general-

ized disease that is almost uniformly fatal in one or two weeks. The naturally occurring infection is transmitted mechanically by biting arthropods, including mosquitoes and rabbit fleas, and artificial infection may be produced by pricking the skin with a contaminated needle.

After multiplication at the site of inoculation, the virus spreads through the lymphatics and into the blood steam and is distributed throughout the body. Both epithelial and connective tissues are affected, with destruction of epithelial cells and proliferation of connective tissue. The lesions in the skin, both primary at the site of inocuation and secondary in the skin, especially about the face and anogenital region, in the lymph nodes, and in the spleen, are tumorous growths. These are characterized by varying degrees of inflammation, the deposition of a glairy mucinous fluid that appears in stained sections as a fibrinous exudate, and the presence of characteristic stellate cells sometimes called myxoma cells.

The myxoma cells are enlarged macrophage-like cells with a heavily staining nucleus, and they contain the virus, sometimes as dispersed elementary bodies in the cytoplasm, but more commonly in intracytoplasmic inclusion bodies closely similar to those found in the pox diseases. 40 The elementary bodies are oval or brick-shaped particles, of the same order of size as those of the pox diseases and molluscum contagiosum.

The virus may be grown on the chorioallantoic membrane of the embyronated hen's egg, where it produces pock-like plaques, and it grows in rabbit kidney tissue culture, ¹⁶ producing inclusion bodies in typical stellate cells. A heat-labile soluble complement-fixing and precipitating antigen is formed in culture and is present in infected tissues and also in the serum of infected animals, but antibody to this antigen is not identical with protective antibody. The virus is closely related immunologically to the fibroma virus (see below).

Myxomatosis has been of considerable epidemiological interest following its deliberate introduction, in 1950 and 1951, into Australia for biological control of the native rabbit population. The unique opportunity to study the natural history of an infectious disease has been thoroughly exploited by the Australian workers.³⁹ The

ME WHO AND AND THE STATE OF THE

Properties of the contract of

disease was also introduced in France in 1952 and spread rapidly throughout Europe.

fibromatosis. This which is transmissible to laboratory (Oryctolagus) rabbits, is similar to infectious myxomatosis, but it is not fatal. The characteristic lesion is a benign subcutaneous spindle-cell fibroma in which there is infiltration of inflammatory cells and hyperplastic and degenerative changes in the overlying epidermis reminiscent of the lesions of molluscum contagiosum in man. Closely similar intracytoplasmic inclusion bodies occur in the affected cells, and also in infected cells in rabbit testis tissue culture, but the virus does not grow in cultures of human foreskin or monkey kidney tissues.62 The contained elementary bodies are closely similar to those of the myxoma virus and poxviruses.

The fibroma virus is immunologically closely related to, but not identical with, the myxoma virus. Animals recovered from fibromatosis are partially immune to myxoma in that they do not contract the disease, but they may be infected and become healthy carriers of myxoma virus. The few rabbits which recover from myxomatosis, however, appear to be solidly immune to fibromatosis.

Fibroma-myxoma transduction. 63 The intimate relation between the viruses of fibroma and of myxoma is indicated by the transformation of the former to the latter by a process which is apparently analogous to the in vivo transduction of pneumococcus types, etc. (Chap. Seven). This was first shown in the rabbit by the simultaneous inoculation of heat-inactivated myxoma virus and living fibroma virus in order to give myxomatosis in the rabbit. This transduction has also been carried out in rabbit testis tissue culture. The transforming agent prepared from myxoma virus is sedimentable by high speed centrifugation and associated with a particle similar in size to that of myxoma virus. It has been suggested that the transforming principle, which is resistant to heat and ether treatment, consists of intact DNA contained within a membrane of denatured protein.

The result is necessarily an alteration in the directed synthesis of viral substance by the host cell initiated by the presence of the inactive virus, and it is of special interest that this can occur in the more complex system involving the host-parasite relationship as well as within the self-contained synthetic mechanisms of bacteria.

INFECTIOUS WART VIRUS

The virus of human warts is a papovavirus closely related to the papilloma viruses rather than to the molluscum contagiosum poxvirus. It occurs in the nuclei of infected cells as crystalline masses. The virus particles have cubic icosahedral symmetry, and are 45 m μ in diameter. The virus has been grown in cell cultures83,92 and found to be infectious for man. Previously the disease had been transmitted from man to man with the production of warts after an incubation period of some months. The lesion, essentially a proliferation of the Malpighian layer of the skin, is usually benign and tends to regress in time, but genital warts may become malignant.

RABBIT PAPILLOMA VIRUS¹²²

Infectious rabbit papillomatosis, described by Shope and Hurst in 1933, is transmissible by cell-free filtrates and is of viral etiology. The virus has been prepared and studied in highly purified form²⁵ and found to be a spherical particle, 40 to 50 m μ in diameter, morphologically indistinguishable from the viruses found in human warts⁸¹ (see above). It resembles other viruses in chemical composition, containing 8.7 per cent nucleic acid of the deoxypentose type, but less lipid, 1.5 per cent, than many other viruses.

Infectious papillomatosis. The disease in cottontail rabbits is characterized by warty growths on various parts of the body. It may be transmitted serially in these animals but not all are susceptible, and in half or more of those infected there is eventual regression of the papillomata; malignant change is rare. The domestic rabbit is much more susceptible, for papillomatous disease develops readily; the tumors grow in benign form for some months and then become malignant, killing the animals. The disease in the domestic rabbit usually cannot be transmitted by cell-free filtrates in serial passage, and the presence of the virus in the affected tissue is indicated by the antibody response.

Pathogenesis of papillomatosis. The pathogenesis of this disease has been one

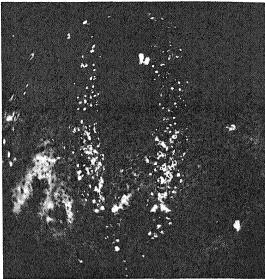

Figure 274. Rabbit papilloma. Left, a paraffin section stained with hematoxylin and eosin and showing the basal, granular intermediate and the superficial keratinized epithelial layers of the papilloma. Right, a frozen section treated with fluorescent antibody for the Shope viral antigens; the localization of the antibody in the nuclei of the keratinized epithelial cells of the papilloma is shown by the bright areas. × 100. (Mellors.)

of the most thoroughly studied of diseases of this kind, and in at least some respects may be regarded as a prototype. The histopathology has been summarized by Kidd.61 On inoculation of the scarified skin the virus induces a prompt and marked proliferation of the epidermal cells, those of the stratum spinosum showing perinuclear vacuolation and dyskeratosis, but the cells mature to a point. They do not form the characteristic horny layer, but rather an atypical cornification occurs in which each cell is surrounded by a layer of keratin and fuses with adjacent cells to form a honeycomb structure, and the cell contents disappear. With extension at the base, the developing cells are pushed into folds and papillae, and keratinization without desquamation results in the horny mass rising above the level of the skin and constituting the benign papilloma. Viral antigen is demonstrable in the nuclei of the keratinized epithelial cells by the fluorescent antibody technique as illustrated in the accompanying figure.

The benign papillomata develop and persist in this form for some months, but eventually there is an abrupt change in the growth, occurring within a relatively short time in all of the lesions on a given animal. Histologically, the germinal cells, which to this point are arranged in an orderly

syncytium, assume a disorderly arrangement, are devoid of perinuclear vacuoles and keratohyalin granules, and do not undergo the abnormal cornification described above. They displace the cells of the basal and spinous layers and undermine the horny mass, which sloughs off. This new type of cell then breaks through the basement membrane, invading contiguous tissues, metastasizes, and assumes the character of a squamous cell carcinoma. Until this last stage, serological evidence indicates that the virus persists in the affected tissue. both in the original animal and in recipients of tissue transplants, but eventually the virus seems to disappear entirely.

Factors affecting malignancy. While it seems clear that at least the initial proliferative response which gives rise to the benign tumor is induced by the virus, there is no evidence that the virus plays a significant part in the subsequent change to malignancy, and there is some reason to believe that other factors may be involved. For example, the benign papilloma can be made rapidly cancerous by the application of carcinogens such as methylcholanthrene and tar-induced epithelial tumors to bring about an abrupt change to malignancy; in the latter instance the virus would appear to behave as a carcinogen.

VACUOLATING VIRUS^{56, 119}

This papovavirus, also known as SV40 (simian virus 40), is commonly found in rhesus and cynomolgus monkey kidney tissue, and was originally discovered as a contaminant of kidney cell cultures and of living virus vaccines, notably the attenuated poliovirus vaccines, prepared in such cultures. It is readily cultivable in grivet, vervet, and patas monkey kidney cell cultures, and in rhesus testicle cultures, to give a unique cytopathic effect characterized by ballooning and vacuolation of the infected cells. In newborn hamster kidney tissue culture it induces malignancy as evidenced by marked growth stimulation.98 It also produces tumors on inoculation into neonatal hamsters.31,43 It is immunologically unrelated to the polyoma virus.

VIRAL AGENTS OF MOUSE NEOPLASTIC DISEASE

The mouse suffers from a variety of neoplastic diseases, susceptibility to which often has a genetic background, and has been an extremely useful experimental animal.

Polyoma.^{30, 47, 118} Various kinds of tumors may be produced in mice by the inoculation of cell-free extracts or filtrates of mouse tumors, including leukemic tissue, shortly after birth. For the most part multiple effects are produced; *i.e.*, it is ordinarily not possible to predict the location or character of the neoplastic growth so produced.

A possible viral nature of the activity present in such cell-free preparations is suggested by its small size and separation from intact tumor cells. The activity demonstrable in cell-free preparations of several mouse tumors has been found to be cultivable in mouse embryo tissue culture, producing a cytopathology characterized by the appearance of small patches of pyknotic cells which progresses until the majority of the cells are affected in two weeks. The activity increases from 10^3 TID₅₀ at two weeks to as much as 106 TID₅₀ at three weeks, and the infectivity for intact experimental animals is correlated with the cytopathic effects and is neutralized by antiserum. The viral agents so cultivated are nonspecific with respect to the type of neoplastic growth produced in the intact animal and have been designated polyoma virus. The virus is spherical, 30 to 40 m μ in diameter, and resembles the other papovaviruses in its properties.

A total of 23 kinds of different primary neoplastic lesions, including pleomorphic tumors of mucous glands, adenosarcomas, renal and bone sarcomas, and epidermoid carcinomas, are produced. It is of interest also, and in contrast with the genetic element in the occurrence of mammary adenosarcoma in the mouse, that such growths are produced regardless of strain of mouse and can be produced also in hamsters.

Animals can be passively immunized to the virus, providing that antiserum is given prior to, or admixed with, the inoculum, but not when serum is given as early as one hour after inoculation. The infection appears to be common in mice in latent form, perhaps because of immunity, initially of maternal origin. Viral activity is present in the neoplasm, but when the tumor is passaged by transplantation viral activity may disappear in the course of time, perhaps after 10 transplants, even though the tumor remains transplantable. The nature of refractoriness to transplantable tumor is not dependent upon antibody and is of particular interest.

Leukemia. 45, 86, 102, 113 Although Rous described cell-free transmission of chicken sarcoma many years ago, interest in this aspect of neoplastic disease remained essentially dormant until Gross demonstrated the viral etiology of a mouse leukemia in 1951 to initiate a period of intense interest and activity. Since then a number of leukemogenic viruses, active in various inbred strains of mice, have been described. The majority produce lymphocytic neoplastic disease, but some produce reticular cell neoplasms and myeloid neoplasms. These strains have been derived from spontaneous leukemias and other neoplastic disease, and from such disease occurring in irradiated animals. They differ somewhat in particle size, over a range of 70 to 100 m μ , and are immunologically distinct but show some interrelationships. They are commonly identified by the name of the investigator(s) who originally described them; the first is the Gross strain, and the others are the Kaplan, Schoolman and Schwartz, Moloney, Friend, etc., strains. The origins and properties of these strains are summarized in the accompanying table.

Murine Leukemia Viruses*

STRAIN (INVESTIGATOR)	ORIGIN	HOST SUSCEPTIBILITY

Mammary carcinoma.^{22, 88} Three factors are involved in the development of mammary adenocarcinoma of the mouse, viz., the genetic constitution of the animal, estrogenic stimulus, and a filterable activity present in cell-free preparations or milk factor. While the milk factor persists and increases in amount in the tissues of the host, hyperplasia of mammary acini occurs only in conjunction with estrogenic stimulation. Some of these become malignant adenocarcinomas, but the relation of the milk factor to malignancy is not clear.

Attempts to characterize the activity have been only partially successful. It is widely distributed in the tissues of mice harboring it, and various tissue extracts are as effective as milk. It obviously increases in amount in that it is transmitted serially in mice under natural conditions. It passes the usual bacteria-proof filters such as the Seitz and Berkefeld. It is highly active, in dilutions as high as 10⁻⁶ in breast tissue extracts. The activity is resistant to tryptic digestion and is destroyed by heating tissue extracts to 60° C. for one hour. It is sedimented at 23,000 × G

in 90 minutes, and some workers have reported that the activity is associated with spherical particles about 30 m μ in diameter, but there is no unequivocal evidence that these represent virus particles. Cell-free activity does not replicate in the embryonated egg but may be recovered from tumor tissue carried for as many as eleven passages in the chick embryo. Attempts to characterize the activity chemically and immunologically have given essentially negative results.

VIRUSES OF AVIAN NEOPLASTIC DISEASE¹⁰⁶, ¹²⁶

The viral etiology of what is now known as the avian leucosis complex was described by Ellermann and Bang in 1908 and the fowl sarcomas transmissible by cell-free filtrates by Rous in 1911. The former is an infectious disease characterized by an autonomous proliferation of cells of hematopoietic tissues. The Rous sarcomas have

been thought to originate in monocytes or histiocytes, but there is evidence that the host cell of the causative virus is the fibroblast. In contrast with rabbit papillomatosis, malignancy is appararent at the initiation of these diseases.

Avian leucosis. 10 Avian leucosis is not a single disease, but a complex of a variety of forms of disease. Beard, Sharp, and Eckert¹¹ divide this complex into two categories, the one lymphomatosis and the other erythromyeloblastic leucosis. In the former, cells of lymphoid origin are involved, the affected cells occur in fixed tissues rather than in the circulation, and the disease process varies with respect to the localization of the primitive cells affected, viz., neurolymphomatosis, visceral lymphomatosis, isolated lymphosarcomatous tumors, etc. The second group is made up of erythroblastosis and myeloblastosis, or a combination of both as erythromyeloblastosis, and is characterized by the occurrence of very large numbers of primitive cells in the circulating blood.

While these diseases "breed true" in that cell-free filtrates of lymphomatosis produce lymphomatosis, and erythromyeloblastosis is similarly reproduced, cellular transfer of the former has resulted in the latter disease. It is quite uncertain whether the several differentiable conditions are produced by a single virus, by variants of a single virus, or by a group of closely related viruses.

Erythromyeloblastosis. While a particulate component has been isolated in studies on lymphomatosis, the most detailed studies have been carried out with the virus of erythromyeloblastosis, and it may be considered here as representative.

There is a great technical advantage in the study of this virus, for it is present in the plasma of infected chickens in such large amounts that the plasma is literally turbid, and it may be sedimented by high-speed centrifugation. The virus particle is spheroid in shape, with an average diameter of about 120 m μ , and is apparently a relatively fragile structure, for it is pleomorphic in dried preparations, like the virus of Newcastle disease.26 Its chemical constitution is not known with precision, other than its relatively high content of lipid, as much as 30 per cent, in contrast to rabbit papilloma virus. It is of special interest that it contains adenosine triphosphatase activity, which appears to be an integral part of the virus particle.

The serum of infected chickens does not

ordinarily contain antibody to the virus in regularly demonstrable amounts, but it functions as an antigen in concentrated preparations. Three kinds of antigens are found, one also present in normal chicken tissue, heterophile or Forssman antigen, and virus-specific antigen. The occurrence of host-specific antigen in purified preparations of viruses is commonly assumed to be, and probably often represents, contamination. Such antigen present in influenza virus is suspected to be an integral part of the virus particle, but in the case of this leucosis viral antibody to the chick tissue antigen and that to Forssman antigen, as well as antibody to the virus-specific antigen, neutralize the viral activity, which appears to establish all three kinds of antigens as structural components of the virus.

Fowl sarcoma.^{50, 105} Rous and his associates were able to transmit several types of chicken sarcomata by means of cell-free filtrates to produce in the recipients under appropriate experimental conditions the same kind of tumor. That designated tumor 1, which has been used extensively for experimental purposes, was a spindle-cell sarcoma characterized by free metastasis and the production of disease fatal in about a month. Tumor 7 was an osteochondrosarcoma, and tumor 18 a spindle-cell sarcoma characterized by the presence of blood sinuses in which growth occurred.

It was early observed that, after several transplants, variations began to occur in tumor 1 as indicated by the appearance of spherical rather than spindle cells and hemorrhagic growths, changes possibly attributable to variations in host resistance as well as in the tumor. Other variations may be produced experimentally. When inoculated in very large amounts in ducks this virus produces two kinds of tumors. The one appearing only after several months is no longer effective in adult chickens and produces a generalized disease characterized by periosteal sarcomata in the duck, while the other which appears much earlier is not found to be modified on subsequent infection of the chicken. The variation apparent in the first instance can be reversed by inoculation of the variant into young chicks to produce again the two types of lesions found in ducks, one of which represents the reversion. Other variants produced in ducks have been found to have altered tissue specificities in chickens, and still other

variants have been produced in turkeys and guinea fowl.

The virus of tumor 1 has been prepared in purified form by both chemical and physical methods, beginning with its salting out by half-saturated ammonium sulfate in association with a nucleoprotein fraction. There appears to be some variation in the size of the infective particle, and it is usually given as within the range 70 to 100 m μ . Particles of this size have been reported to occur in the affected tissue, for example as round or oval bodies within the walls of vacuoles of the cells, showing a double limiting membrane surrounding a central electron-dense body,32 but in general it has not been established that such bodies are virus particles. Purified preparations of the virus give about 8 per cent total nitrogen, 35 per cent lipid, and 1 to 2 per cent pentose nucleic acid. The virus has been grown in tissue culture.⁷⁶ high dilutions of inoculum producing, in chick embryo tissue culture, discrete foci of cytopathology in the monolayer, characterized by a swelling and granularity of the cells and eventual displacement of the nuclei, proportional in number to the infectivity of the inoculum.

The antigenicity of purified virus preparations is separable into two components, the one having virus specificity and the other that of normal chicken tissue; whether the latter represents an integral part of the virus or contamination is not clear. It is of particular interest that some of the tar-induced tumors are immunologically related to the Rous sarcoma 1 virus; for example, pheasants inoculated with a nonfiltrable tar-induced sarcoma produced antibody to the Rous virus. It has been reported also that certain carcinogen-induced tumors are subsequently transmissible by cell-free preparations.

THE MYXOVIRUS GROUP (INFLUENZA, MUMPS, MEASLES, RUBELLA, RABIES) AND RELATED VIRUSES

Disease of the respiratory tract in man is of heterogeneous etiology, the causative agents ranging from bacteria and Mycoplasma, through fungi, rickettsiae, and psittacosis-ornithosis organisms, to various kinds of viruses. Acute respiratory disease, often referred to as ARD, is thus etiologically complex, though perhaps less so clinically.

Elucidation of the viral etiology of a portion of diseases of this kind was initiated with the isolation and characterization of influenza virus in 1933 through reproduction of the disease in the ferret. Subsequent development of more sophisticated tissue culture techniques, coupled with the availability of antibiotics to minimize the effects of bacterial contamination of specimens such as nasopharyngeal washings, while not affecting the proliferation of the virus, made possible wide application of this method and the isolation of a series of hitherto unknown viruses. 124 The extension

of readily applicable serological methods of characterization and identification as a corollary to tissue culture methods, and the application of such serological methods to the retrospective diagnosis of infections of this kind, allow estimation of the relative prevalence of such viruses in the host population. In consequence, a general pattern of viral infections of this kind is beginning to emerge, 25, 103, 125 although many gaps remain and a considerable portion of undifferentiated acute respiratory disease, or ARD, remains of as yet unknown etiology.

The viral agents of ARD are diverse, including not only the influenza and related viruses of the myxovirus group, but also adenoviruses, and certain of the enteric viruses (picornaviruses) associated with the common cold syndrome. The myxoviruses and adenoviruses will be considered here, and the picornaviruses, including those producing respiratory disease, elsewhere (Chap. Thirty-nine).

The Myxoviruses

The viruses of the myxovirus group, socalled because of the affinity of some for mucinous substrates (see below), are ether sensitive DNA viruses in which the nucleic acid is considered to be single-stranded; the capsid has helical symmetry with a helix diameter of 9 to 17 m μ ; and the mature virus particle, assembled at the host cell surface but completed outside the cell, is enclosed in an envelope.

This group of viruses tends to separate into two subgroups, designated subgroup I and subgroup II, or myxovirus and paramyxovirus, on the basis of size and cytopathic effect (CPE) produced in cell cultures. The first group is somewhat more uniform and smaller in size, 80 to 120 m μ versus 150 to 250 m μ . The myxovirus CPE in cell culture tends to be degenerative in type, while that produced by the paramyxoviruses is syncytial in character and eosinophilic inclusions are found in the cytoplasm of the affected cells. The myxovirus subgroup includes the influenza viruses and probably the rabies virus, and the paramyxovirus subgroup the parainfluenza, mumps, measles, and Newcastle disease viruses.

Hemagglutination. These viruses act as hemagglutinins as do the arboviruses (Chap. Forty), but are distinguished from the latter by their content of neuraminidase, which degrades the receptor substance on the red cell to allow spontaneous elution. Some other viruses, such as certain of the poxviruses, produce a soluble hemagglutinin but the virus particle does not act as an agglutinating agent.

Hemagglutination by myxoviruses provides a convenient method of in vitro titration of the virus; i.e., serial dilutions of virus-containing material, such as allantoic fluid, in red cell suspensions show an end point that is a measure of the viral concentration, which has been particularly useful with the influenza viruses (see below). Agglutination of red cells also occurs about centers of viral proliferation in cell culture sheets, i.e., plaques, and occurs prior to, or in the apparent absence of, CPE; the phenomenon is termed hemadsorption. Viral hemagglutination is specifically inhibited by antiviral serum, and the hemagglutination-inhibition (HI) test may be used to titrate antiviral antibody (see below).

When the virus-agglutinated red cells are allowed to stand for a few hours, the virus

particles are spontaneously eluted in consequence of degradation of the red cell receptor substance, and are no longer agglutinable by the addition of fresh virus. Neuraminidase is also produced by a number of bacteria, notably *Vibrio cholerae* and *Cl. welchii*, and treatment of red cells with cell-free supernatants of liquid cultures of such bacteria renders them inagglutinable by myxoviruses; neuraminidase of such bacterial origin is commonly called receptor-destroying enzyme, or RDE.

The cell receptor substance is a mucoprotein, protein conjugated with oligosaccharides. The size of the oligosaccharide groups and the number of them attached to the protein vary. The terminal units of the oligosaccharides are acetylated neuraminic acid residues, attached by a glycosidic linkage to the adjacent sugar. It is this linkage which is destroyed by neuraminidase, or RDE, with consequent breakdown of the orderly arrangement of groups apparently necessary for the adsorption of virus.

The myxoviruses are not identical in that, while red cells treated with one virus are no longer agglutinated by, or adsorb, that virus, they may or may not adsorb other viruses of the group and be agglutinated by them. This has led to the formulation of a receptor gradient series: mumps → NDV \rightarrow influenza A \rightarrow swine influenza \rightarrow influenza B. Red cells treated with mumps virus will still agglutinate in the presence of NDV and the influenza viruses; those treated with NDV will not be agglutinated by mumps virus or NDV, but will be agglutinated by the influenza viruses; etc. This relationship is not absolute but is dependent upon the amount of virus used and the length of time it is allowed to act upon the red cell.

Aside from its practical utility, the myxoviral hemagglutination reaction, and its mechanisms, are probably related to the initial stage in the proliferation of these viruses, e.g., adsorption to the surface of the host cell.

The Influenza Viruses

Influenza¹¹⁹ is a widespread disease of man occurring in sporadic interepidemic form, in periodic epidemics, and in pandemic form. Pandemics occurred in 1890 and in 1918–1919; in the latter the disease

occurred all over the world, and the estimated number of deaths was over 21 million. The epidemic periodicity differs somewhat between the two main types of influenza virus (see below), and epidemics of greater

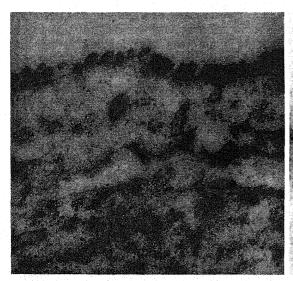

or lesser extent occur at two- to three-year intervals in the case of influenza A and at four- to five-year intervals with influenza B. The epidemic periodicity appears to be due to the accumulation of susceptibles, and the subtraction of immunes by death, in the population, but pandemic influenza seems to be a result of antigenic changes in the virus of sufficient magnitude that there is little effective cross-immunity between the pre-existing and new antigenic types.

The prevalence of the infection is indicated by the occurrence of demonstrable serum antibody in practically all adults and in most children over five years of age. It is probable that many infections are subclinical, or mild and regarded as common colds, and that the viruses persist in interepidemic periods in the form of such infections and as sporadic cases. There seems to be no unequivocal evidence of the existence of a chronic carrier state. Such persistence of these viruses perhaps contributes to the maintenance of observed antibody titers in the general population.

Morphology. 67, 133 The influenza viruses are morphologically indistinguishable, but there is some evidence that certain strains of influenza B are slightly larger than influenza A strains. As described elsewhere (Chap. Three), on primary isolation in the embryonated egg, and often for the first

few passages, the virus occurs as both spheres and filaments; both have viral activity, and there is some reason to believe that the spherical particles may differentiate from the filamentous forms. Spherical particles cut centrally in ultrathin sections are found to contain a central body 20 to 22 m μ in diameter which is surrounded by less dense material and a limiting membrane about 3 m μ thick.⁸⁸ Analysis of purified preparations has given a chemical composition of 60 to 70 per cent protein, 5 per cent carbohydrate, 20 to 30 per cent lipid, and about 1 per cent nucleic acid of the pentose type.

Toxin. 31, 74, 75, 87 Like certain other viruses, the influenza viruses are toxic in high concentration, and the toxicity persists after appropriate inactivation, as by ultraviolet irradiation, but is destroyed before hemagglutinin and antigenic activity. The toxicity is demonstrable by intracerebral inoculation in the mouse with symptoms referable to meningoencephalitic changes observed at autopsy. On intravenous or intraperitoneal inoculation the toxicity is pyrogenic in the rabbit, and fatal toxemia in the mouse is associated with liver and spleen damage with hyperemia, and with focal necrosis in the former and destruction of the malpighian bodies in the latter. The toxicity may be neutralized by antiserum

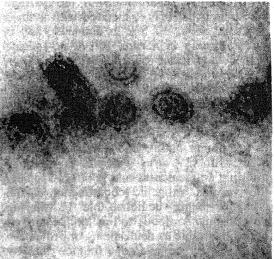

Figure 275. Ultrathin sections of entodermal cells of chorioallantoic membrane infected with influenza virus. Left, the virus particles in the form of spheres and short rods are on the surface of the cell, and the cell nucleus is below. \times 45,000. Right, a similar preparation at higher magnification showing the spherical bodies to consist of an internal body, a sharply defined dense membrane, and a less dense envelope. The obliquely sectioned rod appears to have an amorphous interior. \times 152,000. (Morgan, Rose, and Moore: J. Exp. Med.)

and is group-specific between influenza A and B with some strain differences observed. It is of some interest also that animals may be protected against the toxicity by pretreatment with neuraminidase, suggesting that the toxicity is related to attachment of the virus particle to the host cell.

Hemagglutinin.21 The red cells of many species of animals are so agglutinated, and those of the chicken, man, and the guinea pig are usually used. The hemagglutinin activity is intimately associated with the virus particle but may be separated from it by ether extraction. In fresh preparations the hemagglutinin activity parallels infectivity closely and is used as a measure of virus concentration. It is not, however, identical with infectivity; infectivity is destroyed at 42° C., leaving hemagglutinin activity unimpaired; after treatment at 56° C. the hemagglutinin is adsorbed on red cells but will not elute, and following treatment at 65° C. it is not adsorbed. The hemagglutinin of human strains is inactivated by trypsin, but that of swine influenza is not. The relative sensitivity of the human strains appears to be correlated with antigenic tvpe122 (see below).

Antigenic structure. Two kinds of antigens are present in these viruses. One is the soluble or S antigen, which is found free in infected tissue, is also present in the virus particle from which it may be extracted, together with hemagglutinin, by ether, and is irregularly separable from the particle by sonic lysis. It is associated with a small particle, about $10 \text{ m}\mu$ in diameter, and is nucleoprotein in nature. It is type-specific and demonstrable by complement fixation in the presence of antibody, and antibody to it is formed in response to infection, but not ordinarily in persons immunized with inactivated partially purified virus.

The second kind of antigen or V antigen is protein in nature and intimately associated with the virus particle. It contains multiple antigenicities and is strain-specific, the various antigenic components of the complex being demonstrable in varying proportions. Antibody to this kind of antigen is demonstrable as neutralizing or protective antibody, by complement fixation and by the hemagglutination-inhibition, or HI, reaction. The last serological reaction is simple to carry out. The hemagglutinating unit (HU) of virus is determined by serial dilution and is represented by the highest dilution pro-

ducing hemagglutination in 0.5 per cent erythrocyte suspension. Serial dilutions of the serum are titrated against four HU, and the end point is the highest dilution of serum that will prevent, or inhibit, the viral hemagglutination. The end point of hemagglutination, or hemagglutination-inhibition, may be measured with greater precision on the basis of optical density of the red cell suspension.⁸⁵

Nonspecific, i.e., nonantibody, inhibitors of a mucinous nature are often present in serum or tissue extracts, but only to low titer, and may be eliminated by pretreatment of the serum with RDE. Since the HI antibody is strain-specific and parallels, although it is not identical with, protective antibody, it is an extremely useful reaction for antibody surveys, is applicable to antigenic analysis of virus strains, etc.

It has long been known that host-specific antigen, derived from the host cell, is present in the virus. This kind of antigen is now established as occurring in the envelope in intimate association, but distinct from, hemagglutinin.⁶⁸

Antigenic varieties. The influenza viruses are separable into at least three main types which are immunologically distinct from one another, viz., type A, which was isolated in 1933; type B, isolated in 1940; and type C, isolated in 1949. Each of these types is made up of strains, related to one another by the type-specificity of the S antigen, but differing to a greater or lesser extent in the antigenic specificities contained in the V antigenic complex, and it has become almost axiomatic that a newly isolated strain will not be immunologically identical with strains isolated at other times. Such strain differences are demonstrable by the neutralization or protection test and by the HI reaction.

Type A influenza virus is the most common cause of influenza in man and shows the greatest strain variability. It has been possible, largely on the basis of the effectiveness of prophylactic immunity, to separate the multiplicity of type A strains into four main subgroups. The first of these is the swine influenza subgroup, strains of which were responsible for the 1918–1919 pandemic which persisted for perhaps 10 years as a cause of human influenza as indicated by serological evidence (see below). The first human strain to be isolated, the WS strain in 1933, is not identical with swine

889 VARIATION

influenza but is more closely related to it than subgroups found later. The second subgroup is typified by the PR8 strain of virus. The human strains isolated in 1933 to 1935 were of this subgroup and were responsible for type A influenza for another 10 years. The third subgroup is the A-prime (A')group, of which the FM1 strain is generally taken as a prototype. It appeared in 1946. and strains of this subgroup were responsible for human type A influenza through at least 1956. The fourth subgroup is that of the Asian strains which first appeared in 1957. This, in turn, has undergone antigenic variation.95 This time sequence in the appearance of antigenic subgroups is of particular significance in connection with naturally occurring antigenic variation (see below) and has practical consequences to effective prophylactic immunization.

Type B influenza viruses are also variable, but only two main subgroups are distinguished on the basis of the protective effect of immunization. The Lee strain is a prototype of the first of these, and Lee vaccine continued to give an effective prophylactic immunity until as late as 1954, although strains isolated somewhat earlier were found to be more distantly related to it. The second subgroup, representing successors to the Lee subgroup, has as its prototype the GL strains and additional antigenic variation has occurred. 109 Type C influenza viruses are less common than types A and B and appear to be more stable in that, while strain differences are apparent, these are not sufficient for the separation of subgroups, and in general the type C viruses are relatively homogeneous. The type C viruses have not been associated with epidemic disease in man, and, in fact, their relation to clinical illness is somewhat obscure.

Variation. There are three general kinds of variation among the influenza viruses, viz., variation in hemagglutinin species-specificity, variation in pathogenicity which perhaps includes hemagglutinin, and antigenic variation. There is also a variation between strains in their sensitivity to the nonspecific hemagglutinin inhibitor present in human and animal serums which appears to breed true even on continuous passage. On primary isolation the virus grows more readily in the amnionic than the allantoic cavity of the embryonated hen's egg and usually agglutinates fowl erythrocytes to a much lower titer than guinea pig or human O red cells, and the latter is expressed as the F:G hemagglutinin ratio. The primary isolate is said to be in the original, or O, state. After passage in the egg, the virus will grow in the allantoic cavity, is pathogenic for the mouse, and the F:G ratio approaches unity. Continued passage in the embryonated egg also often results in a rapid loss of virulence for man. When the virus shows these characteristics it is said to be in the derived, or D, state, and this change is the O-D variation which has its analogies with other microorganisms; the general phenomenon is discussed elsewhere (Chap. Seven).

Other changes may be induced by continuous passage, viz., the endotheliotropic variant produced by passage on the chorioallantoic membrane and the neurotropic variant resulting from passage in the mouse brain. As described elsewhere (Chap. Four), the inoculation of a nonadapted strain into the mouse brain results in an incomplete growth cycle with the appearance of noninfective or incomplete virus. There is also another kind of variation in hemagglutinin activity, characterized by partial or complete cross HI reactions in which three phases, designated P. O. and R. may be distinguished, which seems to be a consequence of differences in avidity of the hemagglutinin for antibody.

Antigenic variation. Variation in the constituent antigens of the V complex occurs with some facility under natural conditions, and similar changes may be induced in the laboratory. When the subgroups are separated, as noted above, the naturally occurring phenomenon appears to be a continuous variation in the antigenic character of type A virus, with occasional major changes of sufficient magnitude that there is no effective cross-immunity so far as man is concerned. The cross-reactions between major representative strains in the HI reaction are illustrated in the accompanying table. In the case of influenza B viruses, the second subgroup seems to have differentiated as a result of cumulative changes rather than a single major change. The evidence for this is of two kinds. One is the direct demonstration of antigenic differences in isolated strains, and the other is that of retrospective serological diagnosis in relation to age groups.

spect to specificity and age group reflect the prevalence in time of the subgroups of influenza A virus. In one such study completed in 1953, and later fully substantiated by studies both in this country and in England, it was evident that the serum of children contained antibody to the then only recently prevalent A-prime strains; that of individuals in the 15- to 28-year age group contained antibody to the PR8 subgroup as well; and antibody to the swine group, as well as to subsequently appearing antigenic varieties, was found only in persons at least 30 years of age. It is of special interest that, with the appearance of the Asian strains, antibody to this subgroup has been found in persons 70 to 90 years of age, suggesting that this apparently new antigenic variety may have been present in 1890.33, 108 The implication, of course, is that of the possibility of cyclic change, perhaps affected by human life span, rather than the appearance of new antigenic varieties in indefinite extension.

The validity of inferences as to a succession of antigenic varieties from the age distribution of serum antibody specificity is dependent upon the nature of the immune response in man.⁶⁴ It is suggested by data such as the foregoing, and has been substantiated experimentally, by immunization with monovalent vaccines of representative antigenic varieties, that (a) the initial or childhood experience reflects the dominant

antigens of the prevalent strains and is of limited effectiveness since the disease is most prevalent in this age group; (b) successive subsequent infections with differing antigenic varieties of the virus both reinforce the initial response and broaden it with the acquisition of new antibodies; and (c) the wide range of antibody activity in the serum of older persons is a consequence of contact with a broad range of influenza antigens with continuous reinforcement of prior antibody responses and the development of a progressively more effective immunity.

Antigenic variation may be produced under experimental conditions in a number of ways. Double infections with different virus strains result in recombination and the appearance of hybrids as well as parental types⁷⁶ (Chap. Seven) in the same way that bacterial virus hybrids are produced, and similar changes have been produced in mixtures of active and inactive virus which appear to be analogous to the bacterial and fibroma-myxoma virus transductions. Just as the antigenic structure of bacteria may be altered by growth in the presence of homologous antibody, influenza virus is similarly altered in the presence of antibody, both in egg culture and in infected partially immune animals, the changes in antigenic structure persisting in the absence of antibody. Representative changes produced by the latter method and demonstrable by the HI reaction are shown in the accompanying

table. The conventional interpretation is that such antigenic variants arise from mutants and are selected by the antibody present. It is possible that some such mechanism is operative in the appearance of the naturally occurring antigenic variants of influenza virus.

Infection in lower animals. Animals other than man are not, so far as is known, naturally infected with the human influenza viruses with the important exception of swine. Avian influenza viruses, including classic fowl plague, seem not to occur in man. 96

Swine influenza. This naturally occurring respiratory disease was observed in swine in this country at the time of the influenza pandemic in 1918. The etiology of the disease was described by Shope, who in 1930 isolated the swine influenza virus and a porcine variety of Hemophilus influenzae and showed that both kinds of microorganisms were required to produce the clinical disease. He later found a complex cycle of transmission, involving two reservoir hosts. The virus occurs in lungworms in infected swine, and the infected lungworm ova are excreted in the feces, ingested by earthworms, and the larvae develop in the earthworms. The infective cycle is completed when the infected earthworms are ingested by pigs, but the disease does not occur in the absence of some exciting cause, H. influenzae var. suis infection, but climatic conditions may apparently be effective also. The demonstration of the persistence of the infection in this masked form in intermediate hosts¹¹⁸ has been taken by some to suggest the possibility of the persistence of human influenza virus in some masked form, but there is no evidence to support such an inference.

There is little doubt that swine influenza virus is closely related to the influenza A virus strains prevalent during the 1918–1919 pandemic as indicated by serological studies such as those described above, but it seems likely that the animal infection was originally acquired from man.

Experimental infections. The ferret is highly susceptible to intranasal inoculation with the influenza viruses and may, in fact, be infected by contact. On primary isolation of the virus from man, there may be few symptoms of disease in the ferret, but the infection is demonstrable by a rise in antibody titer. On serial passage, virulence increases and there are overt symptoms of disease and lung consolidation. Similarly, the mouse lightly anesthetized with ether may be infected in primary isolation of the old type A strains by intranasal inoculation: fresh isolates usually do not produce lung lesions, but pulmonary consolidation is produced by passage strains of the virus. The Aprime and Asian strains are much less virulent for the mouse, and this animal is not practical for primary isolation of them. Type B influenza virus generally grows poorly in the mouse, even on prolonged passage. The embryonated hen's egg may be infected by various routes, but isolation is most often successful on inoculation of the amnionic cavity of 12- to 14-day old eggs. On passage the virus will grow in the allantoic cavity, in the yolk sac, and on the chorioallantoic membrane. Of these methods of isolation, inoculation of the amnionic cavity of the embryonated egg is regarded as one of the most sensitive.

The disease in man.³² The virus enters the body via the respiratory tract, and the incubation period of influenza is short, one or two days, giving the epidemic and pandemic disease its explosive character. Symptoms referable to the respiratory tract, including nasal, pharyngeal, and laryngeal irritation and associated symptoms, occur but are often subordinate to the constitutional reaction with fever and prostration. The syndrome is variable and not characteristic, and influenza cannot be diagnosed on clinical grounds.

[†]Homologous titers are shown in boldface.

The most common complication, and usually the immediate cause of death in the fatal disease, is pneumonia resulting from secondary bacterial, most often staphylococcal, but also streptococcal or pneumococcal, infection.^{65, 97, 116} Uncomplicated influenza may, though rarely, assume a fatal fulminating form, ⁹¹ and in such instances there is intense congestion of the trachea with consolidation and hemorrhage in the lungs, but little evidence of cellular reaction.

Following an epidemic, the disease becomes apparently less prevalent, but this is a consequence of the occurrence of an increasing proportion of clinically mild infections. Serological studies have shown that the incidence of infections continues, with persistence during interepidemic periods in smoldering endemic form, 62 recurring in severe form when antigenic variation has resulted in the appearance of strains differing sufficiently that the existing immunity is less effective.

Immunity. Recovery from the disease results in the appearance of antibody to both S and V antigens giving complement-fixing, neutralizing, and HI reactions. Effective immunity is associated with antibody to the strain-specific V antigen. It persists for perhaps a few months, and there is evidence suggesting that it may be dependent upon the presence of neutralizing antibody in the respiratory mucosa.

The immunity resulting from initial exposure to the viral antigens appears to be of a low order but, as described above, seems to increase in effectiveness with repeated exposure to the virus so that the total experience of perhaps three decades provides a reasonable measure of effective immunity. This often, but not invariably, modifies subsequent infections so that the disease is subclinical or little more than a mild coryza. Such immunity is not effective against virus strains in which major antigenic changes have occurred.

Laboratory diagnosis.^{23, 78} The differentiation of influenza from a variety of clinically similar conditions is etiological and requires direct or indirect identification of the virus in the laboratory. Direct identification is accomplished most readily by the inoculation of nasal washings, containing appropriate antibacterial substances such as a mixture of penicillin and streptomycin, into the amnionic cavity of the 12- to 14-day

old embryonated egg. Virus is present in the amnionic fluid in two to four days, may be detected by the agglutination of type O human erythrocytes, and may be identified by the HI reaction with known antiserum. The virus may also, but with less certainty, be isolated by intranasal inoculation of the ferret and subsequent demonstration of a rising antibody titer or the presence of the viruses in the lung tissue.

The presence of the virus is shown indirectly by a rising antibody titer in paired serum specimens, the one taken as early as possible in the acute stage of the disease, and the other 10 days to three weeks later. The complement-fixation and HI reactions may be used; the former is less likely to be affected by minor antigenic differences between the test antigen and the infecting virus. A four-fold or greater rise in titer is regarded as diagnostic.

Prophylactic immunization. Prophylactic immunization against the disease is carried out with inactivated virus grown in the allantoic cavity of the embryonated egg and partially purified, commonly by adsorption and elution from chicken red cells. An appreciable degree of effective immunity against homologous or closely related strains of virus is apparent in about a week and persists for some months. The degree of protection conferred is dependent upon the time elapsing between immunization and exposure, and it is estimated that 40 to 70 per cent of persons are protected. 117, 120

Because of the changing antigenic character of virus strains, the vaccine strains are subject to alteration. Vaccine is usually multivalent, containing both type A and type B virus strains, but the type A has been changed from the PR8 strain to A-prime strains such as FM1, and later to include Asian strains, while the type B strains have shifted from the group having the Lee strain as a prototype to later-appearing types such as the GL or Todd strains. As prepared commercially, the vaccines are kept in monovalent form and mixed to give polyvalent vaccine of a composition determined by the nature of current isolates.

The use of living vaccines, consisting of virus adapted to mammalian cells in culture and administered intranasally, has been of interest in Russia and has also been tested in England, but as yet has not proved to be markedly superior to the inactivated virus.

The Influenza-like and Other Respiratory Viruses

A number of viruses other than the influenza viruses have been isolated from a variety of acute respiratory diseases lacking precise clinical characterization and considered to be common colds, pneumonitis, etc., and on occasion, from apparently normal individuals. Some appear to be related to the influenza group, others make up the distinctive group of adenoviruses (see below), and still others are miscellaneous in the sense that they are unrelated to one another or to established groups of viruses. Antibody surveys have indicated, however, that they may be more prevalent than the frequency of isolation would suggest, and their occurrence emphasizes the diverse etiology of acute respiratory disease. 121

PARAINFLUENZA VIRUSES

The viruses now considered to make up the parainfluenza group account for a considerable portion of ARD. Isolated from upper respiratory tract disease of varying severity, they account for much of such disease in children^{26, 27} and are by no means unknown in adults. 19 They are found in this country, in Europe, 123 and in Australia and are no doubt world-wide in occurrence. Although of varied etiology, the disease is substantially the same, resembling a common cold with pharyngitis, rhinitis, bronchitis, and fever, lasting three to four days,94 and tending to be more severe in children. The etiological relation of these viruses to such upper respiratory disease is indicated not only by specific antibody response, but also by experimental reproduction of the disease in human volunteers. 130, 131

It has been observed that when guinea pig erythrocytes are added to monkey kidney cell cultures of influenza virus, the red cells are aggregated about and adsorbed by the cells in which viral proliferation is occurring, as noted above. This is not a unique property of myxoviruses for it occurs also with certain simian viruses and PPLO in cell culture. Certain of the parainfluenza viruses isolated by application of this technique have been called hemadsorption, or HA, viruses. These and similar viruses, described under various names, and se-

rologically distinct, or even unrelated, to one another and to the influenza viruses have been arranged as types of parainfluenza virus.⁸

Parainfluenza 1. This designation includes two viruses which are immunologically related but not identical, the Sendai virus and the HA 2 virus.

virus. (Newborn pneumonitis Sendai virus, hemagglutinating virus of Japan or HVJ, influenza virus type D). This virus, has been isolated repeatedly from both human and animal (swine, mice) sources in Japan since 1952. It appeared to be the etiological agent of highly fatal epidemic pneumonitis of newborn children in Japan and has been found in infants in Moscow and in Germany. It was also associated with an epidemic of influenza in Vladivostok in 1956. It was isolated from affected individuals during the epidemic, and serum antibody to it persisted for some months in the local population.

The virus was originally isolated in the mouse lung, where it produced influenzalike lesions, e.g., consolidation, and is cultivable in the embryonated egg. It grows well in the allantoic cavity, and also on the chorioallantoic membrane where it produces small pock-like lesions or plaques similar to those produced by herpes simplex virus. It produces a hemagglutinin, agglutinating human, chicken, guinea pig, monkey, and mouse erythrocytes, and is serologically related to the influenza viruses, more closely to type B than the other types, and has been called influenza virus type D.

Significant antibody titers to the Sendai virus have been observed in this country. In convalescents elsewhere the HI titers reach levels of 1:32 to 1:64, the complement-fixing antibody titers 1:32, and the neutralizing antibody titers 1:128 to 1:512. In comparison, HI titers of 1:32 or higher were found in 52 per cent of 118 individuals under 18 years of age, and in 37 per cent of 248 individuals over 18 in this country, suggesting a relatively high prevalence of immunizing infection. The virus is, however, related to mumps virus, and some of the observed antibody titers may be a result of prior mumps infection. Four-fold or greater rises in HI antibody titer have also been observed in this country in association with

The first the second of the second of the second

influenza-like disease and with a few cases of infectious mononucleosis.

HA 2 virus. Hemadsorption type 2 virus, together with HA 1, was isolated by the technique described above from children with febrile respiratory disease.26 Essentially no cytopathic effect was apparent in monkey kidney cell culture, although hemadsorption occurred, but in later passages there was a partial cytopathic effect with the appearance of scattered round cells and eventually focal degeneration in the sheet. The culture fluid contains hemagglutinin, and complement-fixing antigen may be prepared from sonic lysate of the culture. Some of the strains will grow in the amnionic cavity of the seven-day embryonated hen's egg. This virus has also been isolated from adults³⁷ as well as repeatedly from children here and in Japan. Substantially the same virus has been isolated in Denmark, where it was called Copenhagen 222. Infections with this virus account for a small portion of adult ARD, in one study the figure given is 2.6 per cent, but it has been reported that 84 per cent of American adults have antibody. The last is taken to suggest that the virus is widely disseminated. The independence of the Sendai and HA 2 strains is indicated by a lack of correlation in antibody found in surveys. The virus is not antigenically related to influenza, mumps, RS or ECHO 28 (Chap. Thirty-nine) viruses. The pathogenicity of the cultured virus has been demonstrated by the inoculation of human volunteers to produce respiratory

Parainfluenza 2.24 (Croup associated or CA virus, acute laryngotracheobronchitis or ALTB virus). This virus was isolated from two of 12 children suffering from acute laryngotracheobronchitis, or croup, by culture in monkey kidney tissue culture. A cytopathogenic effect appeared in three to five days and consisted of the formation of a syncytial mass with loss of cell boundaries and the appearance of vacuoles and granules in the cytoplasm. It has subsequently been isolated both in this country and in England.

This virus forms a hemagglutinin for chicken and human erythrocytes which has the unusual characteristic of producing agglutination at 4° C., but not at 37° C.; in fact, the process was repeatedly reversible by alternate warming and chilling. Red cells treated with RDE were inagglutinable, but after treatment with CA virus were still

agglutinated by influenza viruses types A and B and by Newcastle disease virus. The virus particle was found to be 90 to 135 m μ in diameter.

In five of 11 children with the disease, a rise in antibody titer to this virus was observed. A small number of normal persons were examined, and significant titers of neutralizing antibody were found in four of 16 individuals 34 months old or less and in 19 of 20 individuals 21 to 30 years old. In contrast to the more or less constant prevalence of the other parainfluenza viruses, type 2 seems to be variable in its occurrence; 22 per cent of American adults are reported to have antibody to it.

Parainfluenza 3. This virus was originally described as hemadsorption virus type 1, and was isolated, together with HA 2, from children having acute febrile respiratory disease. It has subsequently been recovered from both children and adults and is apparently widely disseminated, since antibody has been found in 100 per cent of adult Americans examined.

A hemadsorption virus was isolated from cattle suffering from shipping fever (which is also possibly of Pasteurella etiology [see Chap. Twenty-five]) and designated SF-4, and there is serological evidence of the prevalence of the infection in sheep.⁴⁶ This virus is serologically closely related to parainfluenza 3 virus strains of human origin. The relationship is so close that the two appear identical by the conventional serological methods, but small differences are apparent in the immune response of the guinea pig to intranasal inoculation.² Apparently the same bovine virus has been found in Sweden¹³ and serological studies have indicated that the bovine infection is widespread, with 70 per cent or more of cattle giving positive reactions.3,14 It is not known what relation there may be between the bovine and human diseases. An additional serotype, designated type 4, has been isolated which apparently occurs as at least two subtypes.22

Other myxoviruses. Other viruses, overtly similar, but of as yet uncertain status, have been described. An agent associated with human croup and designated U virus has been reported⁹⁸ which resembles parainfluenza 2 in that hemagglutination occurs more readily in the cold than at incubator temperatures. Another virus, the SA virus, has been isolated from hamster brain fol-

lowing inoculation with chick embryo allantoic culture of nasal washings from an individual with acute upper respiratory infection. 115 The hemagglutinating activity for guinea pig erythrocytes is similar to that of myxoviruses, and the cytopathic effect on monkey kidney cultures is that of syncytium formation. It is apparently unrelated antigenically to other known viruses. Still another antigenically unrelated virus with the properties of a myxovirus was isolated71 from a number of persons with upper respiratory illness in monkey kidney cell culture. The cytopathic effect is one of round cell formation, and the virus, designated M-25, is antigenically unrelated to the other myxoviruses. The virus described by French workers as EA 102 isolated from acute febrile respiratory illness in children²⁸ is characterized by a syncytial cytopathic effect in KB cell culture, and is serologically related to the HA viruses, but does not form a hemagglutinin. The status and significance of virus isolates such as the foregoing is uncertain.

RESPIRATORY SYNCYTIAL VIRUS 126 (RS Agent)

This virus, also known as the chimpanzee coryza agent or CCA, was first isolated from chimpanzees having symptoms of respiratory disease, and spontaneous infection occurred in a laboratory worker.

The virus was originally grown from throat swabs on human liver tissue culture, with cytopathology apparent in about a week. This virus did not infect the common laboratory animals.

The virus has subsequently been isolated from children with bronchopneumonia and bronchitis rather than croup,^{7, 18} and in adults as a natural infection associated with mild upper respiratory disease.⁷² Antibody surveys have indicated that the human infection is acquired early in life; in one survey the proportion of individuals with antibody was found to be 8 per cent in children six to 12 months old, rising to 84 per cent in the 15- to 29-year age group, and falling off to 68 per cent in those 50 years or more old.⁵⁸

RS virus is an ether-sensitive RNA virus. 90 to 120 mu in diameter, but differs from the myxoviruses in that it is not cultivable in the embryonated hen's egg and is not hemagglutinating. It is unrelated antigenically to myxoviruses, and antigenic subtypes have been differentiated.29, 137 It is, however, closely similar morphologically to the myxoviruses10, 20 and, like the paramyxovirus subgroup, produces syncytial CPE in cell cultures. It is, therefore, considered to fall into the paramyxovirus group with the parainfluenza viruses. 134 A closely similar virus, but producing a different and unusual CPE, has been isolated from young adults suffering from mild upper respiratory disease.59

The Mumps and Related Viruses

The mumps virus, the Newcastle disease virus (NDV), and the virus of fowl plague are related to the influenza viruses with respect to hemagglutinin activity and affinity for the receptor substance of the erythrocyte and are members of the paramyxovirus group. In the receptor gradient order of inactivation of receptor sites on the red blood cell, the mumps virus and NDV occur at one end of the series; viz., red blood cells treated with mumps virus will still agglutinate with NDV and influenza A virus, those treated with NDV will agglutinate with influenza A virus but not with mumps virus, and those treated with influence

enza A virus will no longer agglutinate with either mumps virus or NDV.

MUMPS

Mumps, or epidemic parotitis, is a highly contagious, widespread, but seldom fatal disease of man that has long been known because of its distinctive clinical character, *i.e.*, swelling and tenderness of the parotid glands and orchitis in a variable but appreciable portion of cases. Some 60 per cent of adults are immune as compared with

90 per cent immune to measles virus. The disease tends to occur in the winter and early spring, with an epidemic periodicity of seven to eight years.

The mumps virus is present in the saliva and may be isolated within the first few days of the disease from the urine. 132 It may be grown in a number of kinds of cell culture. the cytopathic effect differing with the virus strain and kind of cell culture; e.g., on isolation in HeLa cell or monkey kidney cell culture foci of granular degeneration occur, but with adapted strains other effects are produced, varying with the type of cell culture.⁵⁶ Estimations of particle size have varied considerably; a size range commonly given is 90 to 135 mµ, but values as high as 340 m μ have been recorded. In electron micrographs the observed size of the particle varies, and it is probable that infectivity may be associated with particles of different size. It resembles the influenza viruses not only in hemagglutinating activity as noted above, but also in its hemolytic activity in high viral concentration and the occurrence of two kinds of antigens. The S, or soluble, antigen is separable from the infectivity by differential centrifugation and fixes complement in the presence of antibody, and the V, or viral, antigen is found in the infective particle. Infectivity is destroyed by standing at room temperature for a few days or by 0.1 per cent formalin or ultraviolet irradiation with persistence of hemagglutinin and S and V antigenic activity, and the S antigen is relatively thermostable. The V antigen is related to that of the Sendai (parainfluenza 1) virus.⁵⁰

The disease in man. This disease occurs only in man, and there is no animal reservoir of infection, although several species of monkeys may be infected experimentally. The incubation period is about three weeks. A febrile reaction may or may not occur and is followed within 24 hours by enlargement of the salivary glands, usually the parotids but the sublingual and submaxillary glands may be affected also, and there is an edematous infiltration of the adjacent tissues. The swelling may be bilateral, unilateral, or unilateral followed by involvement of the unaffected side within a few days. It reaches a maximum in 48 hours and persists for one to two weeks, though some evidence of swelling may persist for longer periods. Orchitis occurs in perhaps 20 per cent of cases, but the proportion may vary considerably from one outbreak to another, and the involvement is bilateral, in only 15 to 20 per cent.

Symptoms referable to the central nervous system, indicative of meningoencephalitis, occur in from less than 1 to as much as 10 per cent of cases; such cases occurring in the absence of parotitis are often classed as aseptic meningitis. The pancreas, epididymis, prostate, and ovaries are affected only relatively rarely, although some degree of pancreatitis may be more common than generally thought. Involvement of tissues other than the salivary glands may occur prior to or after the parotitis, or even in the absence of parotitis. Epidemiological evidence, supported by a certain amount of experimental data, indicates that a considerable portion of infections may be asymptomatic but, as indicated above, the infection is less prevalent than measles.84

Immunity. Strains of mumps virus appear to be of the same antigenic type, and recovery from the disease results in a solid and lasting immunity, possibly reinforced from time to time by reinfection, and unquestionable second attacks are quite rare. The immunity is demonstrable as complement-fixing, HI, and protective serum antibody and a hypersensitivity giving the delayed type of reaction to intradermal inoculation of inactivated virus.

The complement fixation test is subject to refinement⁴¹ if both S and V antigens are available, because antibody to the S antigen appears earlier, within a few days of onset, and may reach high titer before antibody to V antigen is detectable. Antibody to the S antigen disappears more rapidly, leaving persisting antibody to the V antigen as evidence of past infection.

A fourfold or greater rise in complementfixing antibody titer between paired serums, taken as early as possible in the disease and two to three weeks after onset, is regarded as diagnostic. Serological diagnosis is not important when the syndrome is typical but is of value in meningoencephalitis without involvement of the salivary glands. The hypersensitivity appears too late in the disease to have diagnostic value, and this test should, in fact, be avoided because the intradermal inoculation of inactivated virus often results in increased titers of antibody to the V antigen. Some convalescent serums give cross-reactions with NDV, and with Sendai virus. A skin test for hypersensitivity to the virus has been of interest, but its correlation with an effective immunity is as yet uncertain.⁴⁹

There has been some interest in prevention or modification of the disease, especially with reference to orchitis in individuals past puberty, by the use of pooled γ -globulin or convalescent serum. Such passive immunization has, however, given only questionable results. Active immunization of monkeys and of man with egg culture virus inactivated with ether or ultraviolet radiation has been partially successful. In man a three-fold difference in the incidence of the disease has been observed between immunized and control groups. 63

Experimental infections. Mumps may be reproduced in several species of monkeys by direct inoculation of the gland via Stensen's duct and the infection passed in these animals by inoculation with suspensions of parotid gland tissue. The experimental disease is similar to that in man, with occurrence of parotitis, facial edema, and associated pathology. Suckling mice and suckling hamsters may also be infected, and sufficient infection occurs in the lungs of adult hamsters to induce antibody formation.

NEWCASTLE DISEASE VIRUS⁶¹

Newcastle disease (pseudo fowl pest, pseudo poultry plague, avian pest, avian distemper, avian pneumoencephalitis) is a disease of birds which is occasionally acquired by man through contact with infected birds. The natural hosts include domestic fowl such as chickens, turkeys, guinea fowl, and parrots and wild birds such as sparrows and pigeons. There is some reason to believe that it may have originated in Indonesia, where it was first described in 1926. It appeared in England in the same year and was eradicated by slaughter and terminal disinfection. It has since been reported from all over the world. It was first identified in this country in 1944 but may have been present as early as 1935. The virus tends to be pleomorphic and varies widely in its pathogenicity and tissue tropism, giving an impression that it may be evolving rapidly. It has been of particular interest as a viral agent that may become more closely adapted to man.

Morphology and cell culture. The virus

particle is 80 to 120 m μ in diameter, but is not necessarily spherical, and may be filamentous or sperm-like in shape. The latter form has been reported as having a head 70 by 180 m μ and a tail as long as 550 m μ . It is unusually resistant under both natural and laboratory conditions. In the first instance, poultry quarters may remain infective for many weeks and produce disease in freshly introduced chickens. Under controlled conditions, some strains of the virus have been found to remain infective after exposure to 56° C. for as long as 180 minutes. In dried secretions and tissues viral activity persists for many months, and the virus has substantial resistance to disinfectants such as formalin and phenols, and glycol aerosols have failed entirely to prevent transmission of airborne infection.

The virus is readily cultivable in the embryonated egg and in several kinds of tissue cultures. When it is grown in the allantoic cavity, hemagglutinin is present in the allantoic fluid which falls between those of mumps virus and influenza A virus in the receptor gradient series noted above, and on this basis NDV is regarded as a member of the myxovirus group. Heavily infected allantoic fluid is also toxic, killing mice in one to three days after intravenous inoculation. Intranasal inoculation in this animal produces interstitial pneumonia that is a manifestation of toxicity, for the virus does not multiply in the mouse lung.

Disease in chickens. After an incubation period of four to 12 days, the onset of the disease in chickens is sudden and characterized by drowsiness, rapid respiration, and fever. Even before symptoms appear, the virus is widely distributed in the body. in highest concentration in the lungs and spleen. There is mucous discharge from the beak and nose, diarrhea, cyanosis, and respiratory distress, followed by convulsions and paralysis, with death in about a week. On autopsy multiple necrotic foci are found in the viscera, there are interstitial pneumonia, hemorrhagic patches in the gastrointestinal tract, and localized meningoencephalitis with degeneration and necrosis and hemorrhage. This syndrome is subject to some variation, the respiratory and gastrointestinal symptoms being associated to some degree with Old World virus strains, while the pneumonic and encephalitic manifestations are often predominant in infection with American strains.

The disease is by no means invariably fatal, and, in fact, virulence varies widely between virus strains. Of two strains isolated in this country, for example, one killed 90 per cent or more of naturally infected chickens, while the other killed only 1 per cent. Under experimental conditions, the LD_{50} dose of cultured virus has been found to vary among strains from 0 to 10^8 per 0.5 ml. of allantoic fluid.

Diseased birds are highly infectious, shedding large amounts of virus in secretions and excretions. This, coupled with the resistance of the virus to drying, tends to favor the transmission of variants of the virus. The infection appears to be transmitted largely by aerosols of dried infectious material, but direct contact with diseased birds or infected carcasses may also be a source of infection. Although the virus is present in the blood, there is no evidence that biting arthropods transmit the infection.

Immunity. While there seem to be minor antigenic differences between strains of the virus, chickens recovered from the disease are solidly immune to reinfection. Virus strains of low virulence are, in fact, used as immunizing agents, and are often administered as aerosols. The immunity is associated with the presence of serum antibody. It is titratable as complement-fixing antibody, neutralizing antibody, antitoxic antibody, and HI antibody. Very high titers are found two to three weeks after initiation of the infection, and HI titers of 1:1280 and neutralizing antibody titers of 1:1 million are not uncommon.

Experimental infections. Guinea pigs, rabbits, and pigs are resistant to infection, the pneumonia produced in the mouse is not transmissible in series, but the ferret responds to intranasal inoculation with the production of antibody. Mice, hamsters,

cotton rats, and rhesus monkeys may be infected by intracerebral inoculation to produce meningoencephalitis of increasing severity with passage.

The disease in man. Human infection is not common and appears to be confined almost exclusively to those who are closely associated with poultry, and laboratory infections have occurred. The incubation period is very short, two days or less, the disease is a unilateral conjunctivitis without corneal involvement, and there may be preauricular adenitis, malaise, and chills, but without fever. No fatal cases have been reported, and recovery is complete within two weeks.

Serum antibody may or may not be detectable after recovery, and serodiagnosis is complicated by the presence of nonspecific neutralizing activity in the serum. One of these is heat-labile and destroyed at 56° C. in 30 minutes, and the other is stable to such heating and associated with neutralizing antibody to mumps virus as noted above. It is supposed that at least some strains of mumps virus have antigens in common with NDV. In general, serodiagnosis of the human infection is not dependable.

The number of persons exposed to infection is very large. It is estimated that seven to eight million people are intimately associated with the raising and care of chickens in this country, and several hundred thousand others are concerned with the processing of poultry. All human cases found thus far have been initial infections acquired from infected birds, and transmission from man to man has not been observed. Neither has there been an instance of human infection acquired from dressed poultry. It is highly problematical whether strains of the virus of higher virulence for man may appear.⁶⁰

The Measles (Rubeola) Virus

Measles is one of the commonest diseases of childhood, and the median number of cases reported each year in this country exceeds half a million even though many cases are probably not reported. Man appears to be universally and highly susceptible to this infection, and the disease confers a solid immunity. These two factors combine to make measles the classic ex-

ample of periodicity in the prevalence of infectious disease (Chap. Ten), and it tends to recur in epidemic form at 2- to 3-year intervals. The probability of acquiring the infection is sufficiently great that the disease occurs early in life in most instances, but some individuals escape childhood infection, as in rural or other areas where contacts are less numerous, and the disease

may appear in young adults aggregated in large groups, as in military camps.

Morphology and cell culture. 12 The viral etiology of measles has been known since 1911, when the filterable nature of the infectious agent was demonstrated, and studies with gradacol membranes indicated a particle diameter of about 140 mu. It was grown in chick embryos and chick embryo cell cultures, but with no CPE. It remained poorly known because of the necessity for infectivity assay in monkeys, which are now known to be often immune, until it was isolated by Enders and his co-workers in 1954 in human and monkey kidney cell cultures in which a characteristic CPE is produced. The virus grows in human amnion cells on primary isolation, and has been adapted to a variety of cell lines.81

The virus is, like the other myxoviruses, an ether-sensitive RNA virus, the type of nucleic acid being inferred from the failure of halogenated deoxyuridines to inhibit growth in cell culture, since the uridine compounds are considered to be specific inhibitors of DNA synthesis. The virus particle has helical symmetry, the helices of the central core having a diameter of 16 m μ and a subunit periodicity of 4.5 m μ , with radial projections into the outer envelope in the mature particle. The measles virus thus closely resembles the

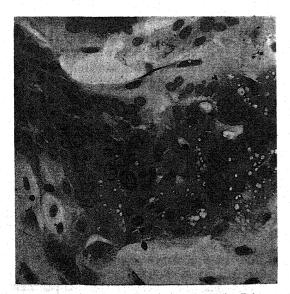

Figure 276. Measles virus in human renal cell tissue culture after 20 days' incubation showing multinucleated giant cell formation and nuclear acidophilic masses. (Enders and Peebles: Proc. Soc. Exp. Biol. Med.)

parainfluenza and other paramyxoviruses in morphology.

In cell culture the CPE is syncytial in character, with the development of eosinophilic cytoplasmic inclusion bodies, the latter providing the basis for the earlier tentative grouping of this virus with the herpesviruses. Complement-fixing antigen is found in culture fluids. The virus is hemagglutinating for monkey cells, and the hemadsorption phenomenon occurs in cell culture sheets. Hemagglutinin-inhibiting antibody occurs in antiserums, and the cell culture system is used for the titration of neutralizing antibody. The virus appears to be antigenically homogeneous, and its marked stability in this respect is indicated by the persisting effective immunity as well as by the failure to find antigenic variants.

The measles virus is closely related to the viruses of canine distemper and rinderpest antigenically, and indistinguishable from them in morphology and CPE, but the latter two viruses are set apart from the measles virus by failure to show hemagglutination. Distemper is a disease of carnivores, including foxes, wolves, and ferrets, as well as the dog, while rinderpest is a disease of cattle and swine. The antigenic interrelations are such that man infected with measles virus produces both distemper and rinderpest neutralizing antibody, infected with rinderpest produce measles neutralizing antibody, but immunization of cattle with measles virus does not protect against rinderpest challenge. Animals infected with distemper virus produce little or no measles neutralizing antibody, but dogs hyperimmunized with measles virus produce antibody to distemper virus. 107

The disease in man.¹²⁸ The infection is probably acquired through the oropharyngeal and ocular pathways.¹⁵ Viral replication occurs in localized areas in the lymphatic system, followed by a transient viremia, during which the virus may be isolated from the blood, and by the appearance of symptoms.

The disease is initiated by prodromal symptoms of a few days' duration which are essentially catarrhal in nature, and include cough and fever. During this period, characteristic lesions, Koplik spots, appear on the buccal mucosa. There are focal exudations of serum and epithelial cells that form vesicles which become necrotic, and their gross appearance is that of a white or bluish white center on an erythematous area.

Koplik spots are diagnostic of measles and occur in 95 per cent or more of cases. Virus is present in the nasopharyngeal and tracheobronchial secretions during this period and for a day or two after the appearance of the rash.

The characteristic macular or maculopapular rash, tending to be confluent, appears within one or more days and spreads over the entire body. The capillaries of the corium are affected first, there is proliferation of epithelial cells, a serous exudate spreads into the epidermis, there is necrosis of epithelial cells, and the rash becomes vesicular. It becomes brownish in a week or 10 days, followed by desquamation.

During the course of the disease there is a general lymphoid hyperplasia, and multinucleate giant cells are found in the tonsils, adenoids, lymph nodes, spleen, and appendix, and in the alveolar and bronchial epithelium in interstitial pneumonitis and what has been referred to as giant cell pneumonia.69 Two kinds of giant cells are found, the Warthin-Finkleday type in the lymphatic tissue, which has nuclei resembling those of lymphocytes and does not contain inclusion bodies, and the syncytial-epithelial type, which may contain as many as 40 nuclei with both cytoplasmic and nuclear inclusion bodies. There is a reduced resistance to secondary bacterial infection,

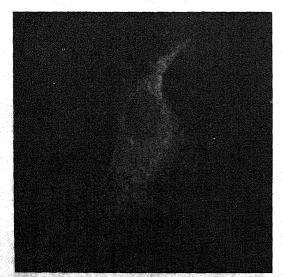

Figure 277. Intracellular measles virus in human epithelial cell tissue culture, treated with convalescent serum and with fluorescein-labeled antiglobulin serum. × 480. (Rapp and Gordon.)

especially with hemolytic streptococci. Encephalomyelitis, with demyelination in the brain and cord, is an uncommon complication, with a case of fatality of perhaps 10 per cent, but more than half the survivors are left with some impairment. Chemotherapy is useful only in minimizing secondary bacterial infection.

Immunity. Antibody is not detectable prior to the appearance of the rash, but thereafter the immune response is very rapid, with the appearance of significant titers within 48 hours. Recovery from the disease is associated with a solid immunity, no doubt periodically reinforced by subsequent contact with the virus, which persists essentially throughout life. Immunization by infection occurs early in life, with perhaps 20 per cent immunes among preschool children, and the proportion rises rapidly to 95 per cent at eight to nine years of age. Complement-fixing, HI, and neutralizing antibody, though maximal in convalescent serums, is present in almost all adult serums.

Immunization. Passive immunization with pooled γ -globulin following exposure to infection may abort or modify the disease, depending upon how soon it is administered; if the disease is aborted there is no active immune response. Pooled γ -globulin, *i.e.*, from adult serums, contains neutralizing antibody to titers of 1:1000 to 1:2000, and HI antibody to titers of 1:128 to 1:51286 which may persist for as long as seven years after the expiration dates of the preparations.

Active immunization.⁴² Attempts to immunize against measles were initiated as early as 1758,³⁸ but it was not until the development of methods of virus culture noted above that the preparation of vaccines became practical. Two kinds of vaccines have been developed, the one inactivated unmodified virus, and the other attenuated living virus.¹²⁷ A number of attenuated strains have been developed by adaptation to growth in various kinds of cell cultures, of which the Edmonston B strain of Enders has been widely used in this country.

Immunization with inactivated virus gives little untoward reaction, and the vaccine is given in multiple doses, usually three, at monthly intervals. In one study⁴⁷ it was found that the vaccine was 82 per cent effective in preventing any evidence of measles and 93 per cent effective in preventing unmodified measles during an epidemic

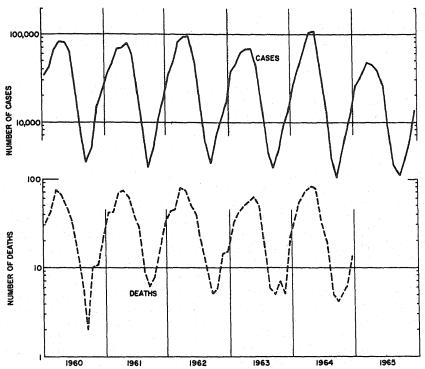

Figure 278. Cases of and deaths from measles reported in the United States during the period 1960–1965. (Morbidity and Mortality Weekly Report, Annual Supplement, Vol. 14, No. 53. Communicable Disease Center, Public Health Service, U.S. Department of Health, Education, and Welfare.)

which occurred seven weeks after completion of immunization. Follow-up for longer periods, including serum antibody titrations, has shown, however, that the immunity so produced tends to be temporary and disappears in a year or two.¹⁰⁰

Immunization with living attenuated virus produces reactions in the form of the mild disease; further attenuation may result in loss of immunogenic potency. Such vaccines have been given alone, with tolerated reactions, or in combination with γ -globulin, to give conversion rates, *i.e.*, appearance of serum antibody, of 97 to 99 per cent. 90 Attenuated virus vaccine has also been given following inoculation with inactivated

vaccine to give an equally satisfactory immune response. Active immunization against measles is now beginning to be widely applied, and its established efficacy more precisely evaluated.

be transmitted to monkeys, both Indian (Macacus rhesus) and South American (M. cynomolgus), by inoculation by various routes, with blood or pharyngeal washings taken early in the disease, but the susceptibility of such animals is irregular. This variability is now known to be a result of the occurrence of immunizing disease in these animals, many of which are found to be immune.

The Rubella Virus 82, 92, 111, 129

Rubella, or German measles, is an exanthematous disease of childhood which resembles measles in many respects but is milder, e.g., the catarrhal symptoms of the prodromal stage are less severe, the subsequent febrile reaction is slight, and the rash

is macular, discrete, or confluent, resembling that of early measles. Koplik spots are not present, and there is characteristic lymphadenitis affecting the cervical and occipital nodes with swelling persisting for two or three weeks. Because of its mild nature it is

not an important pediatric disease, but it has assumed much greater significance in female adults in the child-bearing age group because of its teratogenic effects on the fetus. The association of infection of the mother during the early months of pregnancy with a wide variety of malformations, as well as with abortion and stillbirth, was noted by Gregg in Australia in 1941 and has since been amply confirmed by many observers.

The disease has been assumed to be of viral etiology, but convincing evidence was lacking until about 1962, when several methods of detecting and demonstrating the virus were developed. The fortuitous epidemic prevalence of the disease in the United States and England in 1964-1965 made possible considerable advances in knowledge.

Cell culture. Propagation of the virus in cell culture often produces no CPE. Demonstration of the presence of virus in such cultures is dependent upon its interference with secondary infection with a variety of other viruses, usually of the enterovirus group, which produce CPE; i.e., failure to infect the cell culture with the CPE-producing virus indicates the presence of rubella virus. ECHO-11 was originally used, Coxsackie A-9 has been used frequently, and a number of other viruses may be used also. 93 This indirect, or interference, method may be quantitated to allow the titration of rubella virus as tissue culture interference doses (TCID), and the system is adaptable to the titration of neutralizing antibody. A variation of the interference assay has been described in which Newcastle disease virus, a hemadsorption virus, is used, followed by treatment with bovine erythrocytes to give hemadsorption plaques.80

In certain kinds of cell cultures a CPE. with the appearance of ameboid cells and sloughing, is produced. Primary cultures of human amnion were used by Weller and Neva, the CPE being apparent in five to six weeks. Rubella virus grows to high titer in primary cultures of rabbit embryo cells with the appearance of CPE in six to eight days. 102 Other investigators have used a continuous line of rabbit kidney cell cultures (RK-13) which, with adaptation of the virus, show CPE in about four days, and still others have used a continuous line of monkey kidney cells. When CPE is produced in a reasonable time it allows a practical direct

method of titrating neutralizing antibody. Much of the data presently available on neutralizing antibody have been obtained by the interference type of test, or directly in RK-13 cell cultures: the latter gives somewhat lower titers than the former.

Virus so cultured appears, on the basis of filtration experiments, to be 100 to 300 m μ in diameter, to be of the RNA type, and to generally resemble the myxoviruses. There seems to be only one serological type.

Many attempts have been made to reproduce the disease in experimental animals without success. With the availability of culture virus, it has become clear that subhuman primates and nonprimate conventional experimental animals respond immunologically, often with the production of high titer neutralizing antibody, in the absence of clinical signs of disease. Of the latter, the ferret appears to be one of the most sensitive experimental animals. For the present, studies on the pathogenesis of the disease and evaluation of prophylactic and therapeutic measures continue to depend upon the use of human volunteers.

Pathogenicity for man. As indicated above, rubella is a relatively common childhood disease. With the availability of methods of detecting the virus and the titration of neutralizing antibody, studies on human volunteers infected intranasally with 100 $TCID_{50}$ of virus have shown (a) that the presence of neutralizing antibody prevents the clinical disease; (b) that virus is found in the serum and urine nearly a week before the onset of symptoms, disappearing soon after the appearance of rash and coincident with rise in antibody titer; (c) that virus is recoverable from the nasopharynx in greatest amount coincident with rash and continues to be shed from this area for 10 days to two weeks after the appearance of rash; and (d) that antibody titer continues to rise as long as four weeks after the onset of symptoms. Immunes, i.e., those showing pre-existing neutralizing antibody, not only show no symptoms, but apparently do not shed virus, nor does antibody titer rise.

Immunity is acquired by clinical or inapparent infection, and the proportion of persons showing neutralizing antibody rises with age. Immunizing infection appears to occur through elementary and high school, some 20 per cent of preschool children showing neutralizing antibody, with the proportion rising to 80 per cent in the 17- to 20-year age group. A survey made prior to the 1964–1965 epidemic prevalence of the disease showed that the proportion of immunes increases from about 75 per cent in the 14- to 19-year age group to 89 per cent in the 31- to 44-year age group. The agespecific attack rates observed during the 1964–1965 period were consistent with the assumption that neutralizing antibody is associated with effective immunity to the disease.

The immune status of women in the childbearing age group, 14 to 44, is of special significance because of the teratogenic effects of the infection on the fetus noted above. Several serological surveys have indicated that the overall percentage of susceptibles in this group in cities in the United States is about 17 to 18, and in Hawaii the susceptibility rate was 48 per cent. Canadian studies⁵³ have shown also that antibody titers tend to decline between 25 and 40 years of age. A study of a group of 65 student nurses, aged 18 to 23, exposed to infection and observed over a 12-week period, showed that 17 per cent initially lacked neutralizing antibody, and of this portion 55 per cent developed rubella, about half in clinical form and the other half as inapparent infection demonstrated by virus isolation and the appearance of neutralizing antibody. 112 Much higher attack rates in nonimmunes, nearly 100 per cent, have been observed in military recruits.

Intrauterine infection of the fetus apparently occurs readily in consequence of clinical or inapparent infection as demonstrated by the presence of the virus in aborted fetuses, stillborn infants, and infants with or without abnormalities. In fact, as much as 75 per cent of infected infants were born of mothers with no history of clinical rubella. Infected infants serve to disseminate the infection, often for several months, in spite of the presence of neutralizing antibody.

The teratogenic mechanisms resulting in associated defects remain speculative. The virus may be widely disseminated in the fetus; in fact virus carrier cell cultures have been obtained from congenitally infected infants, ¹⁰¹ and it has been suggested ⁸⁹ that viral proliferation interferes with normal cell growth *in utero*, and possibly subsequently also. The concurrent presence of antibody and virus has been taken to suggest that antigen-antibody reactions, as well as direct effects of the virus, may contribute to the observed consequences of fetal infection. ¹⁶

The isolation and culture of the virus makes possible the development of an effective vaccine, killed or in living attenuated form, but such an immunizing agent is not yet available.

The Rabies Virus¹⁰⁵

The rabies virus, together with poliovirus, is the most highly neurotropic of the viruses. All mammals, and some birds, are susceptible to infection, and in most species, but with important exceptions, it is practically uniformly fatal. The disease, also known as hydrophobia, has been known from ancient times in the Old World in Egypt, Greece, Italy, and other parts of Europe, and the evidence suggests that it was imported into the Western Hemisphere from Europe. Prior to the eighteenth century, it was primarily a disease of wild animals, but in modern times the dog has assumed increasing importance and is responsible for the majority of cases of human infection with the rabies virus. The infectivity of saliva was demonstrated early in the nineteenth century; the virus was studied by Pasteur in the 1880's with the

development of prophylactic treatment and in 1903 was shown by Remlinger to pass bacteria-proof filters.

Morphology and cell culture. Until relatively recently the relation of the rabies virus to other viruses has been obscure. While it is set apart by its marked neurotropism and antigenic individuality, it appears to belong to the myxovirus group. It is an ether-sensitive RNA virus showing helical symmetry and resembling the influenza rather than the paramyxovirus group in its helical diameter of 9 m μ . The virus particle size has been found to range from 160 to 200 m μ by filtration studies, and 110 to 130 $m\mu$ in electron micrographs of negatively stained preparations,5 with a single or double limiting membrane. Projections similar to those found in other myxoviruses have been described.³⁴ Filamentous particles have also been observed which are considered to be unravelling double helices.⁹⁹

While the rabies virus appears to be homogeneous antigenically, a number of antigenic components are demonstrable, ⁸³ and small immunological differences between the usual canine strains and the virus causing paralytic disease in cattle and transmitted by bats are demonstrable by the neutralization test. There are also strain differences in ability to invade the salivary glands.

The virus may be grown in embryonated eggs. Without adaptation, growth in the chick embryo is sufficiently slow that it is outstripped by the growth of the embryo and yields of virus are poor. It may be grown to greater yields in the more slowly developing duck egg, and duck egg virus (DEV) is used as an immunizing agent (see below). The virus may also be grown in mouse brain tissue culture, and in cultures of some nonnervous tissues, viz., newborn hamster kidney fibroblasts, rabbit endothelium, and the WI-38 strain of human diploid cells, but without CPE. In such cell cultures the virus is demonstrable by the fluorescent antibody technique.73 On continued maintenance on hamster fibroblasts or human diploid cells, virus accumulates in the progeny of infected cells in sufficiently large masses that mitosis is inhibited with eventual cell lysis. 45

Pathogenicity.35 The neurotropism of the rabies virus is evident in the pathogenesis of the disease. From the site of the local injury where it is introduced into the tissues, the virus passes along the nerves to the central nervous system; viremia is uncommon, but hematogenous spread may occur under experimental conditions such as infection of the dog by the intravenous route. The significance of the neural pathway is indicated by the experimental infection of nerves, producing infection first in the connected part of the spinal cord, and by the prevention of spread by resection of the nerve, the resected portion remaining infective. There is also evidence that, following its introduction directly into the brain, the virus may spread centrifugally, appearing in nerves such as the brachial and sciatic, producing interstitial neuritis. It has been suggested that the virus reaches the salivary glands in a similar manner.

Infection results in extensive destruction in the cerebral and cerebellar cortices, the midbrain, basal ganglia, pons, and medulla, with neuronal degeneration and demyelination. Similar changes are observed in the spinal cord and are most marked in the posterior horns. There is general hyperemia and mononuclear infiltration, and there may be small perivascular hemorrhages. The extent of these changes is related to the duration of the disease, and when death occurs soon, they may be minimal.

Negri bodies. The acidophilic inclusion body, the Negri body, is pathognomonic of rabies. It is found within the cytoplasm of the large ganglion cells, most abundantly in Ammon's horn, in the pyramidal cell layer of the cerebral cortex and the Purkinje cell layer of the cerebellum, in the cranial nerve nuclei and in the basal ganglia. They are round in shape when lying free in the cytoplasm, may be compressed to an oval form by the nucleus, and are elongated when present in the dendrons. There is a considerable range in size of the Negri body, commonly given as 2 to $10~\mu$, but both smaller and larger bodies may be found.

When stained by Giemsa, the Negri body consists of a light blue ground substance containing red to red-violet basophilic granules. Sellers' stain, basic fuchsin and methylene blue in methanol, is regarded as superior by some workers; it stains the Negri body bright red and the internal granules are blue. The Negri body is stained

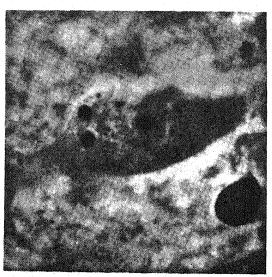

Figure 279. Negri bodies in a nerve cell in a section of the brain of a rabid cat. The three dark spherical bodies within the cytoplasm of the cell are Negri bodies. (Schleifstein.)

specifically by the fluorescent antibody technique which also stains the small eosinophilic inclusion bodies which are not ordinarily considered to be specific.⁵⁴

Negri bodies are not invariably present in infections with canine, or street, virus and cannot be demonstrated in approximately 10 per cent, at times as much as 25 per cent, of infections even though the virus may be isolated. They are not produced, at least not in what is considered to be characteristic size, in infections with the rabbit-adapted, or fixed, virus.

Infection in lower animals. As indicated above, rabies virus occurs in reservoirs of infection in lower animals, most often carnivorous mammals. While practically any mammal, including herbivorous animals, may be infected at one time or another, the kinds of animals providing the reservoir of infection differ from one part of the world to another. The infection is endemic in foxes in Western Europe, and in the wolf in Eastern Europe, and may assume epizootic form from time to time in these animals. In West Africa dogs, both wild and domestic, are commonly infected, and the canine disease is called oulou fato locally, but the epidemiological behavior of the disease suggests that the canine infection is secondary to a reservoir of infection in some small rodent. In South Africa the infection is endemic in small carnivora, the meerkat and related animals, and the mongoose may contribute significantly to maintenance of the infection. In India jackals and wild dogs, and probably the mongoose to a lesser extent, are the important mammalian hosts of the virus.

In North America, Canada is relatively free from rabies,⁴³ but in the southern part of the continent the disease is endemic, and occasionally gives rise to epizootics in foxes in the eastern and southeastern part of the United States, in skunks and other small rodents such as squirrels, raccoons, opossums, and muskrats in the Middle West and West, in coyotes in the West. Larger animals, such as deer may be infected also. In addition to these reservoirs of infection, rabies is also present in bats (see below).

The infection in wild animals may be regarded as the natural form of the disease. It serves as the source of infection for the domestic dog to give an urban type of the disease, the form most important to man.

Rabies in dogs. The infection in dogs is

closely similar to that in wild animals and also to the human disease, and may be considered as representative. Dogs are infected by wild animals, or by other dogs, by the bite of the infected animal. Disease is not inevitable, and an appreciable portion of dogs bitten by a rabid animal, more than half, do not develop the disease. The usual incubation period is three to 10 weeks, but may be as short as 10 days, and under experimental conditions is dependent upon the amount of virus inoculated. The virus is present in the saliva prior to the appearance of characteristic clinical signs of the disease, and the animal is infectious during the last three to five days of the incubation period.

The disease takes two forms, the one furious or mad rabies and the other dumb rabies, depending upon the prolongation of the excitation period. At first the animal becomes restless and apprehensive and may become apathetic or seek out companionship. It then becomes hyperexcitable, responding to minimal stimuli, and runs about snapping and biting without discrimination, apparently oblivious of its surroundings. Beginning paralysis results in drooling of saliva due to inability to swallow, the gait may become abnormal, and the vocal cords are affected to give an eerie quality to the bark or howl. In dumb rabies the phase of excitation is relatively short, the animal appears to be profoundly depressed and unaware of its surroundings, overt paralysis becomes increasingly evident, and in general the more prolonged the disease the greater the paralysis. In either case the disease is practically invariably fatal within 10 days after onset of symptoms, although rare instances of recovery from the paralytic disease have been described. Occasionally death from rabies may occur suddenly without overt symptoms of disease.

On autopsy virus is present in the brain and cord, in the salivary and lacrimal glands, and in the kidney and pancreas, but seldom in the blood, and in general is not found in tissue of mesodermal origin. As noted earlier, strains of virus differ somewhat in their tissue affinities, some strains infecting and multiplying in the salivary glands to a greater extent than others.

The clinical features of the disease are characteristic, and the canine infection is diagnosed by the presence of Negri bodies, but not eliminated by their absence, usually in impression smears of tissue from Am-

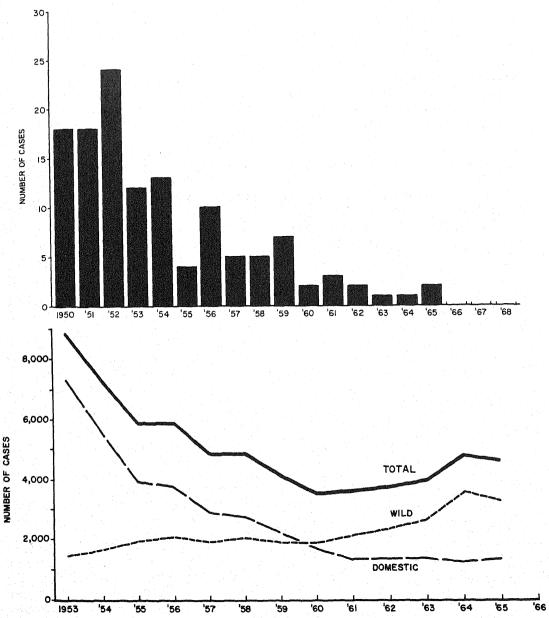

Figure 280. The incidence of rabies in the United States as shown (upper) by reported human cases in the period 1950-1965 and (lower) by reported cases in animals in the period 1953-1965. (Morbidity and Mortality Weekly Report, Annual Supplement, Vol. 14, No. 53. Communicable Disease Center, Public Health Service, U.S. Department of Health, Education, and Welfare.)

mon's horn and/or by isolation of the virus, commonly by intracerebral inoculation of mice. The diagnosis of canine rabies is of practical significance in relation to the institution of prophylactic inoculation in man exposed to infection by the bite of a dog.

Rabies in bats.³⁹ The occurrence of bat rabies, or chiropteran rabies, was first recognized in Brazil in 1908. The infection has

since been found to be widely distributed in vampire bats, of which the most important species in this connection is *Desmodus rotundus murinus*, not only in South America, but also in Central America and Mexico. Since 1953 the infection has been found in a number of species of nonhemophagous bats in various parts of the United States.

The virus found in bats, and in animals

infected by bats, differs from the canine strains in that it produces an ascending myelitis to give a spreading type of paralysis which is almost invariably fatal in animals other than bats. In cattle the hind limbs are paralyzed first, and the disease in man has at times been thought to be an infection with an aberrant type of poliovirus.

While the furious type of rabies is seen in both naturally and experimentally infected bats and is frequently fatal, infectious bats may survive for extended periods, as long as three months, and appreciable numbers survive to become healthy carriers of the virus. Bats are, therefore, an exception to the general rule that the infection is almost invariably fatal. The role of the brown fat in the bat infection has been emphasized by Sulkin and his co-workers. The virus has been isolated from this tissue taken from naturally infected bats, and it has been found that the virus does in fact persist in this tissue, sometimes referred to as the hibernation gland, which functions as a "reservoiring mechanism" where little or no multiplication occurs during hibernation, but on warming the virus multiplies to reach detectable levels in other tissues.4

The vampire bat bites at night to transmit the infection to cattle and other domestic animals and to man. The fatal paralytic disease in cattle has frequently assumed epizootic proportions and is known locally as mal de caderas in Brazil, rabia parisiante in Argentina, and renguera, tronchado, or derriengue in Central America and Mexico. Within affected areas the disease has occurred in 20 to as much as 50 per cent of cattle and other domestic animals. During 1929 to 1931 in Trinidad over 1000 cases occurred each year, and there were 13 cases of fatal human disease in 1929 and four the following year.

Nonhemophagous insectivorous and fruiteating bats in the United States have been found infected in 15 states, ranging from a number of southern states to areas as distant as Montana, Minnesota, Ohio, New York, Delaware, and New England. Eabies virus has been isolated from species of Dasypterus, Lasiurus, Myotis, Tadarida, Pipistrellus, Eptesicus, and Chilonycteris. Of these, the Mexican free-tailed bat, Tadarida mexicana, appears to be relatively heavily infected in Texas, as indicated by an incidence of neutralizing antibody in 16 to 70 per cent, varying with location, of speci-

mens examined. In a detailed study carried out in Florida,⁴⁰ a total of 5503 colonial and free-living bats were examined, and the incidence of infection was found to be 0.2 per cent in the colonial forms and 1.5 per cent in the free-living forms. There appears to be little doubt that the bats constitute a significant reservoir of rabies infection in the Western Hemisphere.

Attenuation. Alteration of the virulence of rabies virus by serial animal passage is the classic example of attenuation of virulence of microorganisms by this method and was applied by Pasteur in his development of attenuated virus for prophylactic immunization. The canine virus, as encountered in nature, was designated by him "street virus." On intracerebral inoculation into the rabbit, disease is produced after an incubation period of about two weeks, but as the infection is passed serially in this animal, the incubation period is progressively reduced, reaching eight days after 20 to 25 passages, and a limit of seven days after another 20 to 25 passages. This modified virus was called "fixed virus" by Pasteur.

Fixed virus is characterized by an enhanced neurotropism, an inability to produce Negri bodies in the infected animal, and a reduced ability to invade the salivary glands. Pasteur's original strain of fixed virus, together with many of its substrains, is still available and has gone through 2000 or more passages in the rabbit. These strains vary among themselves in their virulence, as indicated by differences in incubation period and ability to produce infection by peripheral routes of inoculation in various experimental animals, but in general neurotropism is sufficiently enhanced that they are avirulent for the rabbit, dog, and man by the subcutaneous route. Fixed virus may also be prepared in other animals such as the mouse, guinea pig, or monkey by serial intracerebral passage; on intracerebral passage in the mouse, for example, street virus loses its ability to produce Negri bodies after about 25 passages.

The virus may also be adapted to the chick and chick embryo by continuous passage. The best-known of these strains is the strain isolated by Johnson in 1939 from a human case in day-old chicks and known as the Flury (the patient's name) strain. It was passed 136 times in chicks without observed changes except a decrease in the incubation period from 30 to six days, and

then was passed in chick embryos. After repeated passage in the embryo, its pathogenicity for rabbits and dogs by extraneural routes of inoculation had disappeared, and at the one hundred and seventy-fourth embryo passage intracerebral pathogenicity for the adult mouse was lost, and both dogs and rabbits are resistant to intracerebral inoculation with this high egg passage, or HEP, strain.⁷⁷ Such attenuated strains are of particular interest as immunizing agents.

The disease in man. Human infection with rabies virus is acquired by the bite of an infected animal. The infectiousness of the animal is determined by the presence of virus in the saliva, and it may be present for a few days, probably not more than five, prior to the onset of symptoms. This time element is significant for if the animal does not develop rabies within 10 days, the saliva was probably not infectious at the time of the bite. The incubation period of the human disease ranges from a minimum of two weeks, or possibly slightly less, to as long as five to seven months and is related to the severity of the bite and the location and innervation of the muscle tissue involved. Not all persons bitten by a known rabid animal develop the disease. Whether or not infection occurs is influenced by factors such as the severity of the wound, the removal of saliva when the bite is through heavy clothing, etc., but among equally severely bitten persons less than half may develop the disease. There is evidence that the infection may be acquired by other routes, possibly by inhalation, in caves frequented by bats,³⁰ and an association between such caves and the occurrence of rabies in foxes has been observed.48

The clinical disease in man is similar to that in the dog. The prodromal symptoms include fever, headache, malaise, nausea, and anorexia, and there is anxiety or depression, and often sensations of itching, burning, or tingling at the site of the wound. The onset of the excitation phase is gradual and indicated by increasing nervousness and apprehension. The characteristic symptom is the painful spasmodic contraction of the muscles involved in swallowing and the accessory muscles of respiration when fluid comes in contract with the fauces, and subsequently suggestion of the act of swallowing may precipitate muscle spasm; this feature of the disease gives it the name hydrophobia. As the disease progresses

there may be muscular contractions and tremor, choking, and resulting cyanosis; convulsions occur, and there is often maniacal behavior. Such periods of excitation may be interspersed with lucid intervals. Death usually occurs during convulsions. In some instances the patient survives the period of excitement and becomes apathetic, stupor and coma follow, and an ascending type of paralysis develops. So far as is known the disease in man is invariably fatal.

The pathological changes in human rabies are similar to those seen in dogs and include some degree of hyperemia and severe neuronal degeneration in the midbrain, basal ganglia, and pons. Degenerative changes are marked in the nuclei of cranial nerves and in the thalamus and hypothalamus, and Negri bodies are present. Neuronal degeneration in the cord is most marked in the posterior horns, and when the bite has occurred on an extremity, the corresponding posterior horn shows extensive destruction with neuronophagia and may extend into the dorsal root ganglia.

Laboratory diagnosis. 106 The laboratory diagnosis of rabies is usually of primary importance in the animal which has bitten or otherwise exposed man. As indicated above, the saliva is infectious prior to the development of symptoms. Premature destruction of the animal is undesirable and if possible the disease should be allowed to develop if present to facilitate diagnosis. Such diagnosis, in lower animals or man, is based on the demonstration of Negri bodies, usually in impression smears of Ammon's horn. Giemsa or Sellers' stain may be used, and the fluorescent antibody technique allows the identification of smaller bodies not ordinarily identifiable as Negri bodies.⁷⁹ The technique may, in fact, be used to identify the virus in the salivary glands of infected animals.55 The virus may also isolated by intracerebral inoculation of mice and demonstration of Negri bodies in the mouse brain.

Immunity. Complement-fixing and neutralizing antibodies are formed in response to immunization with vaccine and in unimmunized individuals during the course of the disease. The immune response to infection is not an effective one in man, nor does antibody activity have diagnostic value except in animals such as bats which recover from the disease. Antibody titrations are useful, however, for assaying the response to

immunizing preparations, identification of virus by neutralization tests, and other experimental purposes.

Prophylaxis. There seems to be no significant change in the antigenicity of rabies virus on adaptation to give fixed virus, and effective immunization to rabies in man and dogs is possible because of the long incubation period in the first instance, which allows sufficient time to induce an effective immune response. Immunization of dogs on a mass basis makes possible the control of the urban type of the disease. The immune response to vaccines is not long lasting, and in the case of dogs must be repeated each year.

The extended incubation period in rabies makes possible the development of an effective active immunity even though the immunization is begun after exposure. Pasteur's original method was the inoculation of the exposed person daily with emulsions of fixed virus in rabbit spinal cord, beginning with cord which had been dried 14 days, and gradually increasing the amount of virus by the use of cord dried for shorter and shorter periods. Subsequently other methods, using gradually increasing doses of active virus or virus inactivated by various chemical and physical methods, have been used. In this country fixed virus in rabbit brain tissue, inactivated by phenol (Semple vaccine), formalin, etc., is given in daily subcutaneous inoculations for a period of 14 or 21 days, and similar preparations are used for the immunization of dogs. Phenolized vaccines may be stabilized by lyophilization and still retain immunogenic potency. All such vaccines contain relatively large amounts of nerve tissue, and there is reason to believe that complications, usually neuritis or myelitis with occasional permanent damage, are in large part the consequence of an iso-immune response to organ-specific antigen (Chap. Thirteen).

Vaccines prepared from egg- or cellcultured virus, and consequently lacking contaminating nerve tissue antigen in large amount, have been of considerable interest. The chick embryo-adapted HEP Flury strain¹¹⁰ noted above is effective for primary immunization of domestic animals, but not of man or subhuman primates, although it may be used for booster inoculation in the maintenance of pre-exposure immunity in high risk personnel.⁴⁴ Vaccine prepared from the HEP Flury strain grown in human diploid cell culture (WI-38) has been found to have greater antigenicity in monkeys, 136 but has not been tested in man. Vaccine prepared from virus cultured in duck eggs, and inactivated with β -propriolactone, is a more effective immunizing agent 6,114 and is used for human immunization, but none of these vaccines equal vaccines of the Semple type in immunogenic potency. Assay of potency is carried out in the United States by the Habel method, the protection of actively immunized mice against 1000 LD_{50} of virus by the intracerebral route. 36

Antiserum contains neutralizing antibody demonstrable experimentally and has been of interest as a prophylactic or an adjunct prophylactic for the human disease. It is evident that if antiserum containing neutralizing antibody is given very soon, within a few days of exposure to infection, it gives an appreciable protective effect, and a combination of antiserum and vaccine has been found to give better protection than either alone. 11, 57, 113

Chapter Thirty-nine

THE PICORNAVIRUSES
(POLIOVIRUSES, COXSACKIE
VIRUSES, ECHO VIRUSES, EMC
VIRUSES, COMMON COLD
VIRUSES); THE HEPATITIS VIRUSES;
THE ADENOVIRUSES

The descriptive term picornavirus covers a group of small (pico) RNA viruses which resemble one another closely in morphology and cytopathic effect (CPE) produced in cell cultures. The term nanivirus (nanus, dwarf) had been proposed for this group, but did not gain general acceptance and has been discarded. The viruses of this group fall into two main subgroups on the basis of the pathogenesis of the diseases they produce. 138 One is the enterovirus group,7, 183, which includes the polioviruses, the Coxsackie viruses, and the ECHO viruses, 113 together with enteroviruses found in lower animals. The other is a large group of antigenically diverse viruses which are etiologically related to the common cold and which have been called rhinoviruses, coryzaviruses, "respiratory" viruses, etc. While the general outlines of this classification, and further subdivision, are apparent, details and matters of nomenclature remain somewhat fluid. 155 The occurrence of intermediate types has tended to blur distinctions, but the proposal that the viruses making up the enterovirus subgroup be designated arbitrarily by number¹²⁰ has not been adopted.

These viruses are 20 to 30 m μ in diameter and ether-resistant, and the contained RNA appears to be primarily single-stranded.

Those which have been adequately studied have cubic icosahedral symmetry and 32 capsomeres; the particle is probably in the form of a rhombic triacontahedron, and there is no enveloping membrane. They grow in a variety of cell cultures, with some strain or type differences, and are found in cytoplasm as masses of orderly arrays of virus particles to give inclusion bodies with a crystalline-like appearance.⁹⁸

The hepatitis viruses are very poorly known, and it is by no means clear that they are related in any way to the picornaviruses. The virus of infectious hepatitis is present in the feces and infection is contracted through the ingestion of contaminated water, so it would appear to be an enteric virus in this sense, though not an enterovirus as the term has been used. The virus of serum hepatitis apparently occurs only in the blood, and its relation, if any, to that of infectious hepatitis, or of either of these to the hepatitis viruses of lower animals, is quite unknown.

The adenoviruses are set sharply apart from the picornaviruses in that they are DNA viruses and generally somewhat larger in size, but these viruses are considered here because of the association of many of them with upper respiratory disease.

The Polioviruses 51, 118

Poliomyelitis (infantile paralysis, acute anterior poliomyelitis, Heine-Medin disease) was differentiated as a clinical entity by Heine in 1840, and described in epidemic form by Medin in 1891. The viral nature of the etiological agent was demonstrated in 1908, when Landsteiner and Popper transmitted the disease to monkeys.

The infection is widely distributed throughout most of the world, and the occurrence of the disease in young children for the most part is, as in many other diseases of childhood, an expression of a high probability of contact with the polioviruses. It is estimated that in Chicago most children have been infected once within the first four years of life, and by the sixth birthday 75 per cent have been infected twice. The age at which primary infection occurs is subject to some variation and is affected by social and economic factors (see below).

The great majority of infections are symptomless, and the disease, paralytic or nonparalytic, appears to be the exception. With the waning of passive immunity of maternal origin, repeated infection, with or without disease, results in an immunity, and most adult serums contain neutralizing antibody which is invariably present in pooled materials such as y-globulin concentrates. The incidence of the disease is similar to that in certain other infections, such as meningococcal infection, in which the causative agent is widely distributed in the human population, but the infection is usually symptomless, and the disease tends to appear in sporadic form or occasionally in epidemics.

Poliovirus. ¹⁷⁴ These are among the smallest of the viruses and estimations of size of the spherical particle, based on differential filtration, sedimentation, and direct observation in electron micrographs, range from 22 to 32 m μ in diameter. The virus particles may occur in orderly arrays and have been prepared in the form of bipyramidal crystals (Chap. Three).

The activity of the virus is stable over a relatively wide pH range, pH 4 to 10, over periods of several days at refrigerator temperature; it is resistant to treatment with glycerol, ether, and 1 per cent phenol but is labile to oxidizing agents and ultraviolet irradiation. It is inactivated in 30 minutes at 50 to 55° C. and destroyed in milk by pas-

teurization. It persists in feces and sewage at refrigerator temperatures for extended periods, for as long as three months, and in water has been reported to be somewhat more resistant to chlorination than the vegetative cells of many bacteria. Its inactivation by formalin has been of interest, since this substance is used in the preparation of inactivated vaccines, and prolonged treatment results in the disappearance of antigenicity. The rate of inactivation is exponential over a considerable range (Chap. Six), but treatment based on extrapolation of this rate has resulted in incomplete inactivation.¹⁷³

Antigenic types. Strains of poliovirus are not necessarily immunologically identical, and these viruses have been separated into three types by the specificity of neutralizing antibody. These types are numbered, and are also designated by the name of the prototype strain, e.g., type 1 or Brunhilde, type 2 or Lansing, and type 3 or Leon. Minor antigenic differences occur between strains of all three types. 54, 196 Of these, type 1 is found most often, but more than one type may occur in a single epidemic. Typing is carried out by cross-neutralization tests, at first with monkeys, but now largely in tissue culture. Of a group of 100 strains of global origin typed in the monkey, 85 were found to be type 1, 12 type 2, and three type 3; of a group of 274 strains isolated in this country and typed in tissue culture, 204 were type 1, 22 were type 2, and 48 were type 3. The distribution of the types appears to be world-wide, but it is uncertain as to whether figures such as these reflect the relative prevalence of the three types in the human population.¹⁷⁷ These types differ somewhat in other ways. For example, the Lansing strain is one of the more readily adaptable to rodents, and the Leon type has relatively low virulence for the monkey. There are also differences in virulence between strains. the Brunhilde strain being one of the more virulent strains of type 1.

Two kinds of complement-fixing antigen are present in the virus which are separable by density gradient centrifugation, fraction C and fraction D, with infectivity associated largely with the latter, heavier, fraction. These antigens are separable by gel-diffusion, and D is heat-labile while C increases in amount on heating, presumably as a

VARIATION 915

result of a D \rightarrow C conversion rather than an unmasking of C.²² The occurrence of these two kinds of antigens resolves to a considerable extent anomalous results previously obtained with the complement-fixation reaction. Some workers have introduced the designation N for infectious antigen and H for heat-stable antigen, *i.e.*, C = H and D = N, since it is not established that all particles which are antigenically C invariably sediment in the C zone characteristic of empty shells.⁹⁰

Tissue culture. Beginning in 1949, poliovirus has been grown in cultures of a variety of tissues, including human embryonic tissues, human foreskin and testis, monkey kidney and testis, and in HeLa cell culture, in the Maitland-type flask culture, and in roller and static tube culture. By appropriate adjustment and timing of inoculums, interference among the three immunological types is demonstrable.

A degenerative type of cytopathology is produced which is clearly apparent in the fibroblastic outgrowth as a progressive granulation and eventual destruction.⁸⁴ The CPE is more pronounced with some virus strains than others; e.g., The Lansing strain is feebly cytopathogenic while the Y-SK strain, also type 2, produces extensive degeneration. Further, pathogenicity in tissue culture and pathogenicity for experimental animals are not necessarily parallel.

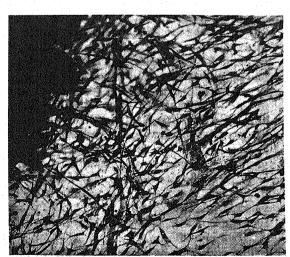

The cytopathic effect is specifically neu-

tralized by antiserum, and thus providing the basis for tissue culture typing of virus strains and may be quantitated for virus assay by the plaque method. ⁴¹ There is evidence that the observed cytopathology is in part a toxic effect of some strains of poliovirus in which the toxicity and infectivity are immunologically independent. ¹

Poliovirus may also be grown in tissue culture by the monolayer technique in which the layer of cells is inoculated, incubated for 45 minutes, and, after the excess inoculum is removed, overlaid with agar. Discrete foci of degeneration, or plaques, occur when the inoculum is sufficiently dilute and may yield differentiable virus strains on subculture.

Variation. Serial passage in tissue culture may result in changes in virulence for experimental animals. The Lansing strain, carried in human embryonic tissue culture, for example, showed a decrease in mouse virulence without a corresponding decrease in virulence for the monkey or alteration in tissue culture infectivity, and the Brunhilde strain, carried similarly, showed a marked decrease in virulence for the monkey. In the same way, after passage in monkey testis tissue culture, the Lansing strain lost its pathogenicity for the mouse but retained its virulence for the monkey, but adaptation to rodent hosts is associated with loss of virulence for the monkey.

Variation in virulence for the mammalian

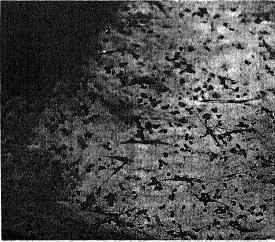

Figure 281. Preparations from roller-tube cultures of human embryonic skin-muscle tissue seven days after cultures were initiated. Left, uninoculated culture; right, inoculated three days previously with the Brunhilde strain of poliomyelitis virus. Few cells remain in the infected culture, the majority having been destroyed by the cytopathogenic action of the virus. Hematoxylin and eosin. (Weller: New Eng. J. Med.)

host may be accompanied by changes in plaque morphology, as in the case of the *d* variant. ^{55, 193} Variants of reduced virulence but with, or perhaps because of, abnormal capacity for growth in tissue culture have been produced by rapid tissue passage with large inoculums by Sabin and his associates. ¹⁶⁹ These have been of special interest as immunizing agents (see below)

The disease in man. So far as is known. natural infection with poliovirus occurs only in man. The virus is demonstrable in the pharyngeal secretions and stools of infected individuals, including contacts who do not develop the disease, and there appears to be a large reservoir of infection in the human population. The infection is spread by contact, though in precisely what way is uncertain, and cases of the disease are distributed radially from an original focus of infection. The incubation period is variable, and is usually given as one to two weeks, although it may be as long as four or five weeks. The clinical disease is separable into three types: the abortive, the nonparalytic, and the paralytic.

The initial symptoms of the disease are those of a mild upper respiratory infection with nonexudative pharyngitis and headache, or of gastroenteritis with nausea and vomiting, but constipation rather than diarrhea, and in either case there is a febrile reaction. When the disease does not develop beyond this point, it is known as abortive poliomyelitis, but it cannot be diagnosed as such without isolation of the virus or demonstration of an increase in antibody titer between paired serums.

The disease may progress with the development of symptoms of involvement of the central nervous system, including pain and stiffness of the muscles of the neck and back and Kernig's sign. This is nonparalytic poliomyelitis. In paralytic poliomyelitis a flaccid paralysis and spasm of unparalyzed or partially paralyzed muscles occur at the terminal phase of the febrile period, progressing for only a short time, usually not beyond 24 hours. Virus disappears rapidly from the spinal cord but may continue to be eliminated in the feces for some time.

The lesions in paralytic poliomyelitis consist of pathological changes in neurons, ranging from mild chromatolysis to complete destruction, and are characterized by local perivascular infiltration with lymphocytes and macrophages, with phagocytosis of the necrotic motor cells. The anterior horn of

the spinal cord is involved, and the destruction of the large nerve cells giving rise to the motor fibers of the peripheral nerves results in the flaccid paralysis. The selective distribution of lesions in the brain is distinctive, differentiating poliomyelitis from the viral encephalitides, in which there is a more or less general diffusion of the virus into the brain. In poliomyelitis the lesions in the cerebral cortex are confined to the motor and premotor areas, rarely extending into the postcentral cortex, and the visual, auditory, and association areas are not involved. There is no impairment of mental faculties, and symptoms of encephalitis disappear when the acute stage of the disease subsides. In the hindbrain the motor cells of the medulla and pons, the vestibular nuclei, and related centers in the cerebellum may be involved, but the neocerebellar complex is not affected. Bulbar poliomyelitis is a consequence of a concentration of neuron destruction in the parts of the medulla containing the motor nuclei of the cranial nerves, with effects ranging from weakness of facial muscles to involvement of the respiratory and vasomotor centers.

Pathogenesis. The pathogenesis of poliomyelitis has been worked out in detail in the chimpanzee and, since this experimental infection appears to be a counterpart of human infection, may be assumed to represent, in a general way at least, the pathogenesis of the human disease. According to Bodian, 17, 19 within a few days after the ingestion of an infecting dose high concentrations of virus are demonstrable in the lymphoid tissues in the tonsils and in Peyer's patches in the intestine. Multiplication of the virus and its excretion from these areas account for its appearance in throat swabs and washings and in the feces. The deeper lymph nodes, cervical and mesenteric, are infected by drainage from these primary sites, and the virus invades the blood stream by way of the lymphatic vessels and the thoracic duct to produce viremia. The viremia is seldom demonstrable in man, possibly because it occurs very early. The infection is spread via the blood stream to various susceptible tissues, including other lymphatic tissue, brown fat, and the central nervous system.

The pathway of invasion of the central nervous system is somewhat uncertain. It may be by way of the blood, but there is also evidence of centripetal spread of the virus along the axons of peripheral nerves, and

Sabin¹⁶⁶ regards the regional nerve ganglia and their connections with the central nervous system as playing a significant role in the pathogenesis of the disease. Virus and lesions are not present in the olfactory bulbs, and virus occurs only rarely in human celiac ganglia, but the vagus and visceral afferent fibers represent a possible pathway from the gastrointestinal tract to the central nervous system. It is also possible that lymphatic tissue is not the exclusive site of multiplication of the virus, but other extraneural tissues may also serve as foci of infection.

The virus is present in the feces and laboratory diagnosis is dependent upon its isolation and serological identification. Monkey kidney, HeLa, KB, and human amnion cell cultures appear to be about equally sensitive for isolation.³¹ Serological identification consists of neutralization in tissue culture with known antiserum¹³² and the fluorescent antibody technique has been applied also.⁷⁶

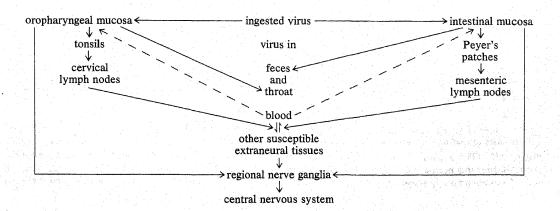

Predisposing factors. In the abortive type of disease, the infection progresses no further than the alimentary or viremic phase, a limited invasion of the central nervous system with reparable damage occurs in nonparalytic poliomyelitis, and extensive invasion and destruction within the central nervous system, which may be largely spinal, or bulbar and bulbospinal, occur in the paralytic form. The factors which determine whether the virus is to enter and multiply within the central nervous system are known in only a limited way.

There is no doubt that specific immunity plays an important part in limiting spread of the infection, but certain nonspecific factors are significant also. Evidence from various sources indicates that injections for immunization of children against diphtheria, pertussis, and tetanus may influence to some degree the site of paralysis in cases occurring up to approximately three weeks following the inoculation, but it is not clear that the incidence of paralysis is affected. 103 It is also established that heavy physical exercise during the prodromal stage of the disease results in more severe paralysis, and paralysis is more likely to occur during pregnancy. An increased incidence of the bulbar form of the disease occurs following tonsillectomy or adenoidectomy. The surgical trauma may open the way for virus already present in the pharynx to gain access to the cranial nerves by which it may reach the medulla directly, or local changes may occur in the permeability of the vascular system supplying the neuraxis. 18, 126 In any case, elective operations in the oropharyngeal area, including dental extractions, should not be performed during epidemics of poliomyelitis, and preferably not during the late summer and early fall, when the prevalence of the infection is high.

There is also no doubt that age is highly significant in the severity of the disease. It is less severe in young children than adults as indicated by an increase in both disability and case fatality with increasing age. The incidence of the more severe bulbar type of infection is appreciably greater in the higher age groups, and the case fatality rate is two to five times as great in adults as in children under five to seven years of age.

Epidemiology. The influence of social

Pathogenesis of Poliomyelitis (after Sabin)

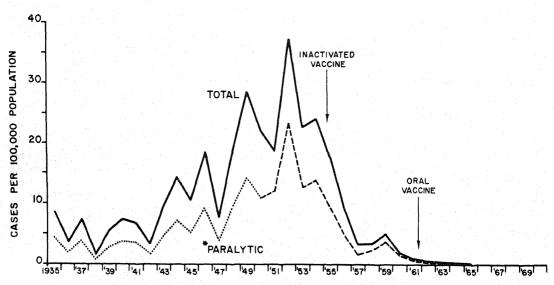

and economic conditions on the epidemiological character of infectious disease has been discussed elsewhere (Chap. Ten) and is nowhere better illustrated than in the changing epidemiological character of poliomyelitis. As indicated above, the virus of poliomyelitis is widely disseminated in the human population, the vast majority of infections are asymptomatic or abortive, and the paraltytic disease is a relatively rare occurrence.

The epidemic described by Medin in 1891 in Sweden is regarded as one of the first epidemics to occur, and the first major epidemic in this country occurred in 1916. Beginning about the turn of the century the disease began to shift from an endemic form. characterized by sporadic cases, to a form in which cases occur in epidemics. The endemic form continues to persist in primitive populations, particularly in tropical areas,2,129 but epidemics have begun to occur in parts of Africa and India, and Japan appears to be in transition from the endemic to the epidemic form of the disease. Coincident with this shift in the character of the disease, the peak in age incidence has shifted from the 0to 4-year age group to the 5- to 9-year age group, and increasing numbers of cases occur in higher age groups and in adults.

This change in epidemiological char-

acter appears to be a consequence of the operation of social and economic factors which postpone the time of primary exposure to the virus. 65, 121 Under relatively primitive conditions, transfer of infection occurs more readily than under more enlightened hygienic circumstances. Primary infection may well occur early enough that passive immunity of maternal origin modifies, in the aggregate, the early immunizing infections, with the result that a pseudoracial immunity develops, and the population is immune to epidemic disease without experiencing clinical disease in epidemic form. By postponement of the first infection, however, the threshold density of susceptibles is raised to a point at which the population becomes susceptible to epidemic disease.

It is sometimes possible to interfere successfully with the development of population susceptibility to epidemic disease by prophylactic immunization. In diphtheria, for example, while the proportion of susceptibles constituting the threshold density is not known with precision, prophylactic immunization of 70 per cent of school age children suffices to prevent epidemics of that disease. Similarly, in poliomyelitis, the development of effective immunizing agents and their application on a sufficiently wide scale may also result in the reversion of this

*PARALYTIC CASES PRIOR TO 1951 ASSUMED TO BE 50% OF TOTAL.

919 **IMMUNITY**

disease to the endemic form characterized by sporadic cases. A trend in this direction, following the introduction of immunization on a wide scale in 1954, is suggested by a rise in the relative incidence of the disease in the 0- to 4-year age group in 1956. Other factors may be operative also; there is, for example, evidence⁴⁸ of a similar trend in some areas in 1948 prior to immunization which may be due to factors such as changing birth rates and the incidence of disease in prior years.

The seasonal incidence of the disease, characterized by a peak in later summer and early fall, was for a time thought to suggest an insect vector. Although virus may persist in muscoid flies under experimental conditions and virus has been isolated from flies having access to human feces during an epidemic, fly control programs have not affected the incidence of the disease, and other epidemiological evidence does not indicate that the infection is transmitted by an insect

vector.

Experimental infections. For many years it was believed that only primates could be experimentally infected with poliovirus. Of such animals available for experimental purposes, the chimpanzee is the most susceptible and has, in fact, been infected accidentally in the laboratory, and the disease in this animal resembles the human disease closely. Of the commonly used monkeys, the cynomolgous monkey may be infected by the gastrointestinal route, and the rhesus is more resistant but may be infected by intracerebral inoculation. The findings at autopsy are similar to those observed in man, with pathological changes, including neuron destruction and perivascular infiltration in the gray matter of the cord.

In 1939 the Lansing strain of virus was adapted from the monkey to the cotton rat and then to mice, and later strains of the other two immunological types have been adapted to mice by introduction of the virus directly into the spinal cord. In such rodents the incubation period is two to 10 days, there is paralysis of one or more legs, few recover, and death occurs from respiratory paralysis. Type 2 strains will also infect hamsters, and one such strain, after many passages in suckling hamsters, has been adapted to the chick embryo. 152

Immunity. The immune response to poliovirus is demonstrable as the presence of complement-fixing and neutralizing antibodies in the serum and a resistance to second inoculation. Serum antibody fixes complement in the presence of tissue culture antigen, but its specificity may overlap the serotypes of the virus, possibly in part because of an anamnestic heterotypic antibody response. Complement-fixing antibody declines relatively rapidly, disappearing in from within a few months to two years. Neutralizing antibody may be titrated in the monkey, but much more readily in tissue culture. Neutralization of the virus is indicated by the lack of CPE or by changes in pH shown by the inclusion of phenol red in the tissue culture fluid. In contrast to complement-fixing antibody, it persists in detectable titer for years. Both kinds of antibody appear quite early in the disease, but if acute phase serum is taken early enough, a rise in antibody titer may be shown to occur between this serum and a convalescent serum taken three to four weeks after onset of the disease.

The presence of neutralizing serum antibody is associated with an effective immunity to the disease. As indicated above, the proportion of individuals showing neutralizing antibody increases sharply with age, and the great majority of adult serums are found to contain antibody. At one time this was thought to represent a "maturation" immunity but, as in many other infectious diseases of childhood, it is now clear that the immunity is a specific response to repeated symptomless or abortive infections which need not progress beyond the alimentary, or possibly viremic, stages to induce the immune response.

Although second, and even third, attacks of poliomyelitis have been found to occur in the same individual, it is probable, although difficult to prove in man, that the second attack is caused by an immunological type of virus different from that of the prior infection. Monkeys recovered from one attack of the disease are solidly immune to inoculation with the same type of virus, but not to heterologous types, and it is possible that this is true in man also. Naturally acquired active immunity in man is probably an immunity to all three types of poliovirus, continuously reinforced by repeated exposure and possibly symptomless infection.

Prophylaxis. Artificially acquired prophylactic immunity may be either passive or active in nature. The source of antibody in the first instance is the concentrated antibody present in pooled γ -globulin. Passive immunization has been shown to be effective in experimental animals and in man has been found to reduce the number of cases of paralytic disease by more than half, providing that the globulin is administered within the first few days of the incubation period, ⁷⁰ but serum therapy of the established disease is ineffective. Passive immunity disappears rapidly, and is no longer effective after about three weeks.

Active immunization. Active immunity may be produced by parenteral inoculation with inactivated vaccine prepared from monkey kidney cell culture, or by infection with attenuated strains of the virus by the oral route. Both kinds of vaccines must include all three immunological types of the virus to provide broad protection.

Inactivated vaccine. Vaccines inactivated with formaldehyde were prepared by Salk¹⁷¹ and are known as Salk vaccine. This kind of vaccine was subjected to extensive field tests, beginning in 1954, and was shown to provide an effective immunity as indicated by a reduction of 70 to 80 per cent in the incidence of the paralytic disease when given as a course of three inoculations, 61, 144 and there is evidence that the disease is less severe in inoculated persons,142 but the immunity is not completely effective.14 A purified vaccine has been prepared³⁵ but its relative efficacy has not been determined. The preparation of an inactivated, yet immunologically potent, vaccine is technically complex, 116 owing to the effect of formaldehyde or antigenicity. The immunity so produced is assayed as protective serum antibody and is presumably dependent upon the presence of such antibody, i.e., such immunization does not prevent the alimentary infection¹⁰⁷ but is effective in the viremic stage and on hematogenous spread of the infection.

Living attenuated vaccine. Virus strains attenuated with respect to neurovirulence have been developed by various workers, largely Sabin, Koprowski, and the Cox-Lederle group, for use as immunizing agents. The stability of such attenuated strains with respect to virulence and associated characteristics has been subjected to intensive study¹⁸⁵ and the probability of reversion to neurovirulence appears to be very small. Vaccines prepared from such strains may be mono- or divalent and given separately to avoid overgrowth and/or interference ef-

fects, or in trivalent form, but only a single dose of a given preparation is required.

These vaccines have been tested in local areas in this country, ^{33, 170} where evaluation of large scale testing is complicated by prior Salk vaccine immunization, and in England, ¹⁴⁵ and field trial has been carried out on a large scale elsewhere, especially in the Soviet Union. ^{37, 178} The results of such testing have been excellent. ^{42, 130, 131}

In addition to the accentuated antigenic stimulus provided by proliferation of the vaccine strains in vivo to give an alimentary infection and the consequent requirement for a single oral, rather than multiple parenteral, inoculation, such immunization differs from that produced by inactivated virus in two significant respects. First, immunization is against the alimentary infection and the immunity may be tested by challenge inoculation with attenuated virus. This kind of immunity tends to depress, if not effectively prevent, dissemination of virulent virus. Second, infection with attenuated virus tends to spread in the community to immunize or reinforce the immunity of others, and there is evidence suggesting that attenuated viruses may displace virulent virus in the intestinal tract. Such a combination of effects is perhaps the basis of the efficacy of oral attenuated vaccine in arresting poliomyelitis in West Berlin at the beginning of an epidemic prevalence. 102 The vaccine also produces an effective immunity in the very young; 75 per cent in newborn and 95 per cent in infants three to six months of age has been described. 79, 127 Considerations such as these have led Sabin¹⁶⁸ to suggest that poliomyelitis may be eradicated in effectively immunized areas.

ENCEPHALOMYELITIS OF MICE

A spontaneous encephalomyelitis of mice of viral etiology was described, by Theiler in this country, by Gildemeister and Ahlfeld in Germany, and by Iguchi in Japan, in the 1930's, which is characterized by a flaccid, poliomyelitis-like paralysis. The infection is widespread in laboratory mice. The virus is present in the intestinal tract and mesenteric lymph nodes of most mice four to six weeks of age and is shed in the feces, but can no longer be found at about six months, and the mice are immune. The dis-

ease can be transmitted to uninfected mice by intracerebral, intranasal, or intraperitoneal inoculation. Following intracerebral inoculation, a flaccid paralysis develops after an incubation period of five to 30 days, and the histopathology includes perivascular infiltration in the central nervous system and necrosis of the ganglion cells of the anterior horn followed by neuronophagia. 110 Rabbits and monkeys are not susceptible, and symptomless infection is produced in suckling hamsters following intracerebral inoculation.

The causative virus is immunologically distinct from the human polioviruses, but it resembles them, not only in the disease produced, but also in its small size, 25 to 30 m μ , and in its resistance to ether and glycerol. The original virus found by Theiler is called Theiler's virus, or TO virus. Two other strains found later, FA and GD7 strains, appear to be less widely distributed. So far as is known, these viruses are nonpathogenic for man. They do constitute an artifact in the use of mice for virus studies; for example, the rodent-adapted strain of Lansing poliovirus became contaminated with FA virus in the mouse and was purified

by passage in the monkey, which is not susceptible to FA virus infection.

TESCHEN VIRUS (Porcine Encephalomyelitis) 34

A highly fatal disease of swine, characterized by a flaccid, ascending paralysis, was first described in the Teschen district of Czechoslovakia as Teschen disease, and spread over Europe under various names such as Talfan disease in England and poliomyelitis suum in Denmark. It is not known to occur in this country. The causative virus is smaller than the polioviruses. 10 to 15 mu in diameter, and is immunologically unrelated to the polioviruses and also to many other neurotropic viruses infecting man. Apparently only the pig is susceptible to infection, and the disease is a diffuse encephalomyelitis affecting the cerebral cortex, the cerebellum, thalamus, basal ganglia, and anterior horn cells of the spinal cord in sharp distinction to the selective localization of the lesions produced by poliovirus.

The Coxsackie Viruses 99, 119

The first of what proved to be a new group of viruses was isolated by Dalldorf and Sickles in 1948 from two children, ill with disease diagnosed as poliomyelitis, by the inoculation of infant mice. Ten additional strains were isolated by Dalldorf the following year, and it was evident that some of the isolates differed from one another. Similar viruses were subsequently isolated by many investigators in various parts of the world. These viruses make up the somewhat heterogeneous group known as the Coxsackie viruses.* or C viruses.

These viruses have been found most often in feces and in sewage and are isolated from time to time from the throat.⁶⁴ They have been found together with poliovirus and during poliomyelitis epidemics in persons not infected with poliovirus. They appear to be most prevalent in the late summer and early

fall; human infections seem to be quite common, as indicated by the presence of antibody to all of the immunological types of these viruses in pooled antibody such as γ -globulin; and they are found in man both in association with disease and in healthy persons

Although of similar size, 15 to 35 m μ , the Coxsackie viruses are distinct from the polioviruses in pathogenicity and immunological character. They are relatively stable over a wide range of temperature and pH; preparations at near-neutrality are still active after long periods at room temperature, and for at least one day at pH extremes of 2.3 and 9.4. They are relatively resistant to substances such as ethyl alcohol, ether, glycerol, and phenolic compounds, but 0.3 per cent formaldehyde is an effective disinfectant.

Infection of cynomolgous monkeys and chimpanzees by the oral route results in a transient febrile reaction, virus is found

^{*}The first strains were found in Coxsackie, New York.

in the pharyngeal secretions and stools, there is a specific immune response, and some strains may produce neuron damage on intracerebral inoculation. Of the more common experimental animals, only the newborn mouse and hamster are susceptible to infection, although some strains occasionally infect adult mice to produce pancreatitis. While this limited host range is a definitive characteristic of the Coxsackie viruses, it does not differentiate them from certain other viruses, the Sinbis and dengue viruses (Chap. Forty), and certain tissue culture-passed strains of ECHO viruses (see below).

Virus types. These viruses are separable into two groups, designated A and B, on the basis of their pathogenicity for the infant mouse and ability to grow in tissue culture, and into immunological types within these groups. The characteristic effect of the viruses of group A in the infant mouse is an inflammatory and degenerative lesion of striated muscle without adverse effect on other tissues. Infected mice show a generalized weakness, a flaccid paralysis develops, and death occurs three to four days after inoculation. At autopsy the skeletal muscles appear white and firm, and a hyaline degeneration is found on microscopic examination.

In contrast, infection with group B viruses

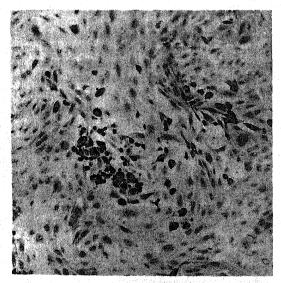

Figure 283. Coxsackie virus type B2 in monkey kidney epithelial cell culture. There are focal areas of cytopathology produced 24 hours after inoculation of the virus; the affected cells are rounded and contain crescentia and pyknotic nuclei, and the cytoplasm shows intense eosinophilic staining. (Enders: Ann. Intern. Med.)

characteristically results in lesions of the central nervous system, with focal leptomeningitis and perivascular lymphocytic infiltration, necrosis of the acinar tissue of the pancreas, hepatitis, and a necrotizing steatitis of the interscapular, cervical, and cephalic pads, and some strains produce focal lesions in the muscles, especially after intraperitoneal inoculation. The occurrence or predominance of these kinds of lesions is variable from one strain of virus to another and is also affected by the age of the mice. Irregular tonic contractions of the muscles prior to death may result in symptoms of "rolling disease" similar to that produced by some of the pleuropneumonia-like organisms (Chap. Twenty-seven). Passage in the infant mouse may be required before the pathological picture becomes characteristic, and the distinction between the A and B groups is not necessarily sharp because of variations in the pathogenicity of virus strains.

There is also a difference between the two groups of Coxsackie viruses with respect to growth in tissue culture. Those of group A are, in general, not cultivable in tissue culture, but the A9 type is an exception, and will grow in monkey kidney tissue culture and in some other kinds of tissue culture also, and has frequently been isolated by this method. Some strains of type A9, isolated in tissue culture, have also been found to be nonpathogenic for infant mice, thus resembling the ECHO viruses. Some group B viruses are cultivable in various kinds of tissue culture, but there is some irregularity in the pattern of susceptibility. Monkey kidney tissue culture, prepared in monolayers, appears to be one of the most generally satisfactory for viruses of group B, and cytopathic effects are produced.

These viruses are also immunologically heterogeneous and, although there may be some overlapping, there appears to be no common antigenicity to bind these viruses together as a group. They are, rather, immunologically individual. A total of 23 specific serotypes has been defined within group A, and six serotypes within group B, and no doubt additional serotypes will continue to be described. These serotypes are given arbitrarily assigned numbers, to give type designations of A1, A2, etc., and B1, B2, etc.

These types are separable by comple-

ment fixation, and by neutralization and protection tests, with substantially the same results. Infected muscle tissue is used for the preparation of immunizing and complement-fixing antigens, and a partial purification of tissue debris may be effected by centrifugation. Protective antibody is demonstrable by the neutralization technique, but infant mice cannot be actively immunized and subsequently challenged because the natural resistance to infection appears very early. An effective passive immunity occurs in infant mice born of and nursed by actively immunized mothers. The protection conferred by active immunity is demonstrable in the chimpanzee as an immunity to challenge inoculation.

The disease in man. As indicated above, serological evidence indicates a wide prevalence of human infection with Coxsackie viruses, and these viruses have been associated with human illness and found in healthy persons. Their association with poliomyelitis appears to be purely fortuitous, and various attempts to demonstrate a potentiating effect of Coxsackie virus infection on poliomyelitis have given negative results. In fact, an interference between some group B strains and poliovirus occurs in tissue culture, and it has been suggested that Coxsackie virus infection may, on occasion, tend to exclude poliovirus infection.

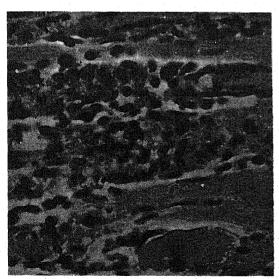

Figure 284. Lesion in striated muscle of a mouse infected with Coxsackie virus. Two sarcolemmic tubes with numerous mononuclear phagocytes and remnants of hyaline material within the sarcolemmic sheaths. Demarcated segmental involvement is apparent. × 500. (Godman, Bunting, and Melnick: Amer. J. Pathol.)

There are, however, some clinical entities with which Coxsackie viruses have been found to be in close, and possibly etiological, relation. These include febrile pharyngitis and herpangina, epidemic pleurodynia, some portion of cases of aseptic meningitis, and myocarditis. The Coe virus, originally isolated from mild upper respiratory disease, has been found to be Coxsackie A21 virus. 176

Herpangina. This is a febrile disease, usually seen in children, which occurs in both epidemic and sporadic form in many parts of the world. There is often vomiting and abdominal pain, and the characteristic lesion is a small, herpes-like vesicle which breaks down to leave a shallow ulcer. These lesions occur on the edge of the soft palate. on the tonsils, in the pharynx, and on the anterior pillars of the fauces. Recovery is usually prompt, within two to three days. and complete. Coxsackie viruses have been isolated from as many as 84 per cent of cases of herpangina examined, and six serotypes, A2, A4, A5, A6, A8, and A10, have been found for the most part, although not exclusively.

There is circumstantial and other evidence, including laboratory infection, which indicates that the group A viruses can produce a febrile pharyngitis, particularly in summer, without the identifying herpangina lesion, giving the disease sometimes known as three-day fever or summer grippe. When the infection takes this form and occurs during epidemics of poliomyelitis, it may be diagnosed as abortive poliomyelitis. Russian workers have, for example, reported a new type of poliovirus, type 4, which was subsequently shown to be Coxsackie virus type A7.81, 194 Or, more severe cases of disease have been observed in which the herpangina is associated with parotitis.82

Epidemic pleurodynia. 10, 56, 165 This disease was first observed in Bornholm, Denmark, in 1930, and is also known as Bornholm disease, epidemic myalgia, and "devil's grip." The disease tends to occur in epidemic form, most commonly in late summer. The incubation period is two to four days, the onset sudden, and the disease is characterized by acute pain in the thoracic wall, abdomen, and lower region of the back and is commonly accompanied by headache, but there are no respiratory or constitutional symptoms. The pain is paroxysmal, lasting a day or more, and the muscles are tender to

pressure. There is a tendency to relapse at intervals of a few days or longer, and orchitis and meningeal involvement may occur.

Strains of group B Coxsackie virus have been isolated from the throat or feces in a considerable portion of cases in several epidemics studied, increase in antibody titer to the virus isolated is observed, and it seems probable that these viruses may be the etiological agents of this disease.

Aseptic meningitis. Aseptic meningitis is a clinical syndrome rather than an etiological entity and may occur in epidemic form. 164, 186 It is usually mild, with signs and symptoms indicating involvement of the meninges. Fever, headache, nausea, pain in the abdomen, and stiffness of the neck or back usually occur. Pleocytosis may be present, up to 100 cells per cu. mm. being observed in the spinal fluid. This disease may be caused by a variety of nonbacterial agents, including Coxsackie viruses. Viruses of

group B—including serotypes B1, B2, B3, and B4, and one of group A, A9, which is set apart from the other group A viruses by its cultivability in monkey kidney tissue as noted above—have been isolated from the feces and from the spinal fluid in cases of this disease. Neutralizing antibody to the isolated virus occurs in the serum, and it is probable that some portion of cases of aseptic meningitis are Coxsackie virus infections.

Myocarditis. 108 In recent years cases of acute myocarditis of infants have been described from various parts of the world. In a few instances isolations of group B Coxsackie viruses have been reported, including recoveries from affected myocardium and from spinal cord. In the latter case, an infant that became ill on the third day after cesarean section and died on the seventh day, serotype B3 virus was found, and the circumstances suggested that intrauterine infection may have occurred.

The Enteric Orphan Viruses 40, 87, 99

With the development of practical and generally applicable methods for the isolation of polioviruses from the intestinal tract in tissue culture, a great many isolations of cytopathogenic agents other than poliovirus have been made. These viruses are previously undescribed entities and, while some have been found in cases of poliomyelitis, often diagnosed as the nonparalytic disease. in many instances there has been no specific association with illness, and they have been called orphan viruses. Those isolated from man have been named the ECHO, or enteric cytopathogenic human orphan, viruses; those from monkeys the ECMO viruses: those from cattle the ECBO viruses; and those from swine the ECSO viruses. Similar viruses isolated from dogs may make up another group of ECDO viruses. Of these, the ECHO viruses have been of the greatest interest, and, with their characterization, some at least have been found to occur in association with, and possibly etiological relation to, human disease.

ECHO VIRUSES

These viruses are similar to polioviruses and Coxsackie viruses in size and have been

found to be about 30 m μ in diameter with the exception of one, ECHO type 10, which has been reported to be 60 to 90 m μ in diameter. They are differentiated from one another by their host range and pathogenicity as expressed in tissue culture, including plaque morphology in monolayer culture, and by separation into antigenic types. Some, though not all, form hemagglutinin²⁸ and are related to one another in this respect, but not to the influenza virus and other myxoviruses.

Culture. In general, the ECHO viruses grow more readily on primary isolation in monkey kidney tissue culture than on HeLa cell culture. This is in contrast to the adenoviruses, which are usually more readily isolated in HeLa cell culture. Many strains of ECHO viruses have been grown in HeLa cell culture, with the appearance of cytopathic effects and complement-fixing antigen in the culture fluid, but the virus titer reached is not as high as that in monkey kidney tissue culture. 6, 125

Plaque morphology. Growth in kidney tissue culture from a variety of species of monkeys has been studied in detail, 84, 85, 86 as has the comparative susceptibility of the cells to these and to poliomyelitis and Cox-

				PLAQUE FORMATION	
VIRUS	SEROTYPE	PLAQUE MORPHOLOGY	RHESUS CELLS PATAS CELLS		
Poliomyelitis		1, 2, 3	Large, circular, sharp boundaries	+	
Coxsackie	B A	1, 2, 3, 4, 5 9	Large, circular, diffuse boundaries, slow development		
ЕСНО	A B	1, 3, 4, 6', 9, 11, 13, 14 7, 8, 12	Small or medium size, irregular, slow development Large, circular	+ + +	

sackie viruses, assayed by the rate of development and morphology of plaques produced in monolayer cultures. It will be recalled that host cell susceptibility and plaque morphology have been established as valid differential characteristics, inheritable and genetically determined, in the case of bacterial viruses (Chap. Three and Seven), and may be regarded as analogous to the morphology of pocks produced on the chorioallantoic membrane by poxviruses and to bacterial colonial morphology on differential mediums. Of the various species of monkeys investigated, the kidney tissue of two, the rhesus and patas (Erythrocebus patus, the African red grass monkey), have been of considerable differential value.

On monolayers of rhesus cells, the polioviruses produce circular plaques with clear centers and sharp boundaries as illustrated in the accompanying figure. The plaques formed by the Coxsackie viruses which are cultivable in tissue culture, group B and A9, develop more slowly, and the boundaries are not sharp owing to the persistence of living cells at the periphery. The plaque-producing ECHO viruses are separable into two groups. One, designated group A and containing serotypes 1, 3, 4, 6', 9, 11, 13, and 14, produces slowly developing, small to medium size, irregular plaques, and group B, consisting of serotypes 7, 8, and 12, produces large circular plaques.

The susceptibility of the two kinds of monolayer kidney cell cultures is also differential. Poliovirus and ECHO group B form plaques on both kinds of cells, but the Coxsackie viruses and ECHO group A form plaques on rhesus cell cultures but not on patas cell cultures. There is further differential susceptibility within the ECHO viruses in that serotypes 2, 5, and 6 do

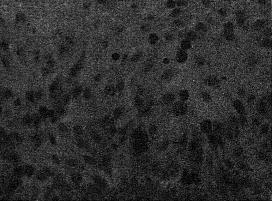

Figure 285. The cytopathic effect of ECHO virus type 1 in culture of monkey kidney epithelial cells. (Melnick: Adv. Virol.)

not produce plaques on either kind of cells, and they are cytopathogenic for rhesus cells but not for patas cells in tube cultures with fluid overlay.

Antigenic types. The ECHO viruses are separable into serotypes by cross-neutralization tests in tissue culture, and standard antiserums are used for identification.⁹⁷ The test is made sharply specific by titration of the 50 per cent tissue culture dose, the TCD₅₀, and the prototype strains have been numbered on an arbitrary basis.

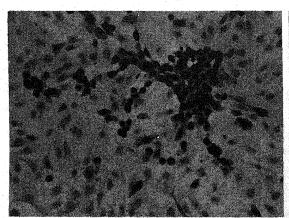

New serotypes continue to be described, to give a total of 33 by 1965. These may be described under other names and subsequently assigned to the ECHO group. For example, the JV viruses¹⁵⁹ are considered to be ECHO viruses, the JV-4 strain being ECHO-25; the Puerto Rican strain PR-10 is ECHO-32;²⁴ and that originally described as Toluca-3 is ECHO-33.¹⁵⁸ Similarly, the respiratory viruses, JH and 2060, were subsequently designated ECHO-28, and still later assigned to the newly described rhinovirus group (see below) and considered to represent type 1 of this group.

Strains within a serotype are not necessarily antigenically identical, and those with broader antigenicity than the prototype strain have been called prime strains. Strains within type 6 have been studied in this connection, and the strains designated 6' and 6'' have been found to have a broader antigenic specificity than that of prototype strain 6. There are cross-reactions among types 1, 8, and 12, ECHO 4 antiserum

neutralizes adenovirus 8, and Coxsackie B4 is neutralized by antiserums to several ECHO types.

Pathogenicity.¹⁷² In a general way, the ECHO viruses are set apart from the Coxsackie viruses in their lack of pathogenicity for the infant mouse although, as noted above, occasional Coxsackie strains are not pathogenic for the infant mouse on primary isolation. While originally found in the absence, or apparent absence of specific disease, certain of the ECHO viruses have been found in association with human disease, especially aseptic meningitis.

Types 4, 5, 6, 9, and 16 have been found repeatedly in cases of aseptic meningitis in the absence of other causative agents, and types, 5, 6, and 9 have been isolated from the spinal fluid. 49, 114, 143 Epidemic aseptic meningitis occurred in Europe in 1955 and 1956, and spread to this country in the following year, in which type 9 appeared to be the etiological agent. The virus strains found were apparently antigenic variants of the prototype strain. Infections associated with type 9, and also with types 4 and 16, have often been characterized also by the presence of a rash. In view of its association with aseptic meningitis, the status of ECHO type 9 is of interest; certain of the apparently more virulent strains, i.e., isolated from spinal fluid, have been found to become pathogenic for infant mice after tissue culture passage, producing myositis and paralysis, and might be considered to be a type B Coxsackie virus.

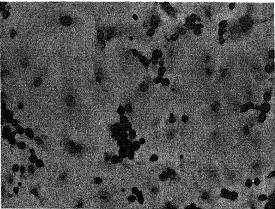

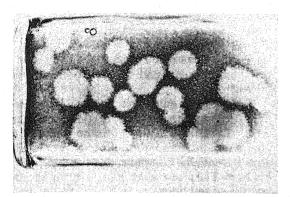

Figure 286. The cytopathic effect of ECHO virus type 1 in culture of monkey kidney epithelial cells. Left, 66 hours after the inoculation of virus; right, 90 hours after the inoculation of virus. At 66 hours there are foci of rounded, densely stained cells and infected cells scattered over the cell sheet. At 90 hours many infected cells have become detached from the glass, most of the remaining cells are rounded because of viral infection, but some normal-appearing cells are still present. Carnoy fixation; hematoxylin and eosin. (Melnick: Adv. Virol.)

REOVIRUSES167, 181

As noted above, the virus of ECHO type 10 is set apart from the other viruses of this group in that it is considerably larger. It forms hemagglutinin for human O cells but not for chicken, guinea pig, sheep, or bovine erythrocytes; the red cell receptors are not affected by RDE but are destroyed by treatment with periodate. There is a distinctive cytopathic effect in monkey kidney cell culture, with granular degeneration of the cells leaving intact nuclei, and intracytoplasmic inclusion bodies are present. These and other distinctive characteristics83 have led to the separation of ECHO 10 strains as a separate group designated reoviruses, the term referring to both respiratory and enteric origin.

Strains of this group contain a common. or group-specific, complement-fixing antigen, and are separable into serotypes by neutralization and hemagglutination-inhibition tests.154 Three serotypes are distinguished. Type 1 consists of the Lang strain, found in healthy children, as the prototype and includes the simian virus SV-12, and other strains isolated from children with upper respiratory disease. Type 2 includes the D5 strain, found in a child with diarrhea, as the prototype, together with simian strains and others of human origin. Two strains have been suggested as the prototype of type 3, one the Dearing strain from a child with diarrhea and the other the Abney strain recovered from a child with febrile upper respiratory disease,160 and subsequently from nursery children. Type 3 strains have also been recovered from cattle. Types 2 and 3 have been found in wild and laboratory mice respectively. Suckling mice may be infected experimentally, some strains producing clinical disease.

ENTERIC ORPHAN VIRUSES OF LOWER ANIMALS⁹⁶

It was noted above that viruses analogous to the ECHO viruses have been found in lower animals, including monkeys, cattle, and swine. The simian viruses have been of most interest, since they are found both in the bowel³⁶ and in apparently healthy monkey kidney tissue88, 89 used for culture of the poliomyelitis and other viruses. A considerable number of simian strains have been examined for plaque morphology on rhesus and patas monkey kidney tissue culture and for antigenic specificity.84 On the first basis they are separable into three groups: group A, characterized by the delayed development of small plaques on both rhesus and patas cultures; group B, made up of strains forming large circular plaques on both rhesus and patas cultures in which islets of unaffected cells are found; and group C strains, which produce plaques on rhesus cultures similar to those of group B but do not produce plaques on patas cultures. Differentiation on the basis of plaque morphology is not necessarily consistent with antigenic and cross-neutralization is differences. observed between plaque types. So far as is known, these viruses, the ECMO group, are not pathogenic for monkeys.

The Encephalomyocarditis Viruses

encephalomyocarditis, or EMC, viruses are represented by a number of strains which appear to be substantially identical. The first to be isolated, the Columbia SK virus, was found in 1940 in a monkey which had been inoculated with the Yale SK strain of poliovirus, but it is clearly distinct, both in antigenicity and pathogenicity, from poliovirus. The MM virus was isolated in 1943 from the brain of a hamster which had been inoculated with material from a human case of paralytic disease. These two strains were at one time considered to be "mouse poliomyelitis viruses" or murine variants of poliovirus, but it is now clear that this is not true. The strain called the EMC virus was isolated in 1945 from a captive chimpanzee in Florida which had died of acute endocarditis complicated by myelitis. The Mengo virus was isolated in 1948 from a captive monkey in Uganda and later from mosquitoes (Taeniorrhynchus fuscopennatus) and a mongoose in the same area. It has also been found as the causative agent of an epizootic disease of swine in Panama. 124

These viruses are ether-resistant RNA viruses, about 25 m μ in diameter, and fall into the enterovirus subgroup of the picornaviruses. They form hemagglutinin⁴⁶ and, although antigenically closely related, strain differences are demonstrable by the HI reaction. There are also interstrain differences in plaque morphology.⁵⁷

A variety of experimental animals may be infected to produce disease ranging from severe fatal disease to inapparent infection, depending upon the species and age of the animal.100 Rapidly fatal disease is produced in the mouse, hamster, and cotton rat, disease varying in severity in the guinea pig and rhesus monkey, and inapparent infection with no more than a transient febrile reaction in the rabbit and white rat. In experimental animals the virus is pantropic, occurring in the blood and widely distributed in the tissues, including the central nervous system. Degenerative and inflammatory changes are produced in skeletal and cardiac muscle, and the lesions in the central nervous system are those of polioencephalitis, with congestion, lymphocytic infiltration, and focal areas of necrosis in the granular and Purkinje cell layers. Variants have been described which differ in their myocardiotropic and neurotropic properties.⁴⁴

The virus is cultivable in the chick embryo, killing the embryo in three or four days. In mouse muscle tissue culture a characteristic cytopathic effect is produced, with essentially complete destruction in 72 hours.³² They are also cultivable in HeLa and other cell lines.

The disease in man. Human infection with EMC virus has been observed on a number of occasions, and there is also serological evidence of infection in both man and lower animals. Soon after its isolation, a laboratory worker was infected with Mengo virus to give a meningoencephalitis of short duration, followed by rapid recovery. The virus was also isolated from four children in Germany who had indefinite illness with signs of meningeal involvement. An epidemic of mild febrile disease, called three-day fever, occurred in Manila in 1945 and 1946 among American military personnel which serological evidence showed to be an infection with this virus. In these cases the febrile period lasted only two to three days; in some cases there were mild encephalitic symptoms, recovery was prompt and without sequelae, and there was no evidence of cardiac involvement.

The presence of neutralizing antibody in both man and monkeys has been observed in serological surveys in Uganda and Tanganyika, with perhaps 3 to 4 per cent of human serums positive. 11 In this country antibody has been found in human serums with some frequency. Of one series of 300 serums examined, nine were found to contain antibody; of the nine positive serums, three were from convalescents from disease diagnosed as mild aseptic meningitis and five from patients diagnosed as having nonparalytic poliomyelitis. 195 An even higher incidence was reported in another group of serums; 21 per cent of serums from poliomyelitis convalescents and 16 per cent of "normal" serums were found to contain antibody to EMC virus.94 Also in this country it has been found that 18 per cent of rat serums examined contained antibody. 195 The presence of the virus in South America has been shown by its isolation from a monkey, Aotus trivirgatus, in Colombia and by the occurrence of antibody in man in Peru⁹³ and in Panama.⁴⁵ Monkeys may be infected by feeding mouse brain virus, but the evidence in general is taken to suggest that

EMC virus occurs as an infection in rodents¹⁰¹ which is transmissible to man and monkeys by mosquitoes and possibly in other ways as well.

The Common Cold Viruses^{5, 187, 188}

The clinical syndrome characterizing the mild upper respiratory disease called the common cold merges imperceptibly into that of acute respiratory disease which, as noted elsewhere (Chap. Thirty-eight), is of diverse etiology. Mild disease resulting from infection with the parainfluenza viruses, respiratory syncytial viruses, and adenoviruses (see below) may be indistinguishable from the common cold. Nevertheless, the common cold appears to be caused more often by viruses of the picornavirus group, which form a subgroup separable from that of the enteroviruses.^{33, 68}

Rhinoviruses.¹⁹⁰ The first of these viruses to be described were those of the JH 2060 type which, as noted above, were subsequently put into the ECHO group as the ECHO-28 serotype. Closely similar, but antigenically distinct, viruses were isolated in England at the Salisbury Common Cold Research Unit and were referred to as the Salisbury agents and in the United States by Hilleman and his co-workers in Pennsylvania, who designated them coryzaviruses, at the National Institutes of Health, and at the University of Chicago.

For a time these viruses were known as the ERC (ECHO-rhino-coryza) viruses and as the muriviruses (mild upper respiratory illness). The term rhinovirus was proposed on an international basis and is now generally accepted for this group. There is also general agreement on the identification of the serotypes making up the group by numbers based on the chronology of description. To 1967, 55 serotypes have been established and assigned numbers; of these the JH-2060-ECHO-28 virus is rhinovirus 1.

These viruses are ether-stable RNA viruses with a particle size of 15 to 30 m μ , characteristics of the picornavirus group. As a subgroup, they are separable from the viruses of the enterovirus subgroup by their acid lability (pH 3 to 5 for one to three hours) and their relative thermostability at

50° C., which is enhanced by M MgCl₂.52 Some are cultivable only in human cell (embryo kidney or diploid cells) cultures. and others also in monkey kidney and other kinds of cell cultures, with CPE manifested as the appearance of ovoid refractile cells. They are separated into two types on this basis, the H type cultivable only in human tissue culture, and the M type growing in monkey and other cell cultures. In general, growth is better in roller tube than in still cultures, and occurs at 33° C. Growth of these viruses in human embryo trachea tissue, or organ, culture occurs more readily than in other kinds of tissue culture.80 Neutralizing antibody is titrated in cell culture.

Pathogenicity. Serological surveys have shown that the distribution of neutralizing antibody in human serums is world-wide, but neutralizing antibody is not found in serums of lower animals. Presumably the reservoir of infection with the strains found in man is only man, but bovine²⁰ and equine^{53, 137} rhinoviruses have been described. The latter occur as at least two serotypes and infect man in populations at risk, such as stable workers.¹³⁹

The significance of human rhinoviruses in the etiology of the common cold has been demonstrated in a number of studies based on isolation and identification of the associated virus. The spectrum of viruses differs between infants and very young children on the one hand, and adults on the other, the parainfluenza viruses, respiratory syncytial viruses, and other myxoviruses assuming greater importance in the former. 38, 47, 149 In one study⁷⁷ rhinoviruses were found in 4.8 per cent of children and 14.2 per cent of adults, and in another⁷¹ 5 per cent and 10 per cent respectively. Similar results, 17 per cent positive isolations, have been obtained with college students,135 to give good agreement with an average figure of 15 per cent in adults. The predominance of the rhinoviruses was also shown in another study of

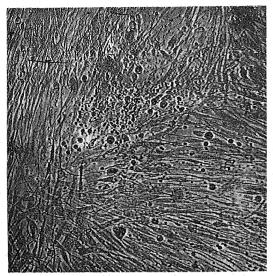

Figure 288. The cytopathic effect (CPE) produced by rhinovirus type 2 in a culture of the W38 strain of human diploid cells. Unstained. (Hamre.)

college students over a period of four years, in which 80 per cent of the total isolations were rhinoviruses of 50 serological types, and of the remainder, most (15 per cent) were myxoviruses.⁷²

Failure to obtain a higher proportion of positive isolations from cases of clinically apparent disease has been attributed to the relative insensitivity of the culture methods, or the occurrence of other as yet unknown viruses not recoverable by the methods used. Support for the former is provided by the higher proportions, nearly twice as many, of positive isolations when embryonic human trachea tissue culture is used. 189

It is probable that the virulence of the rhinoviruses is not great and that most adults have some degree of partial immunity as indicated by serological surveys. Studies on the occurrence of, and immune response to, rhinoviruses 1 and 2 in a military population over a 24-week period (January to June)⁹² showed that both viruses were present during five of the weeks, and one or the other during 16, with isolation rates of 12 per cent. The incidence of positive isolations in those with significant antibody titer was only 20 per cent of that in those persons showing no antibody. It is probable that the respiratory viruses, including the rhinoviruses, persist at a low level of infection, with the development of clinical disease attributable in very considerable part to nonspecific stress.⁴

Immunity. As indicated above, there is an association between pre-existing antibody and resistance to development of disease. Immunization with virus vaccine by the intramuscular route followed by intranasal challenge of small numbers of persons showed an approximate 10-fold reduction in colds in the vaccinated group over those occurring in the control group. 148 Other studies on the effect of naturally occurring vaccine- or infection-induced body response have also shown an approximate correlation between serum antibody levels and occurrence and/or severity of disease produced by challenge inoculation,30 though some irregularities were observed. It has also been generally observed that virus is isolated less often from persons showing serum antibody and such persons tend to carry and disseminate the virus less frequently. While it seems clear that an appreciable degree of immunity to a given virus serotype occurs and can be produced by immunization, in view of the multiplicity of serotypes of rhinoviruses as many as 40 were found in one study⁷¹ and 50 in another⁷² – the practical efficacy of prophylactic immunization to the common cold as a disease entity remains somewhat uncertain.

Foot-and-Mouth Disease²⁷

Foot-and-mouth disease is a naturally occurring, highly contagious disease of cloven-footed animals, primarily of cattle, swine, sheep, and goats, which occasionally infects man. It is characterized by a vesicular eruption on the lips, buccal cavity, pharynx, and extremities, but the causative

virus is quite unrelated to the herpes viruses.

The virus is present in the vesicle fluid early in the disease and may also be present in the blood, saliva, urine, and milk, but disappears within three to five days from the local lesions and the blood. This was the first animal disease shown to be of virus etiology,

by Löffler and Frosch in 1897. The virus is an ether-resistant RNA virus, 22 to 23 mu in diameter,8 and is considered to be a member of the picornavirus group. Like the rhinoviruses, it differs from the enterovirus subgroup in its relative instability at acid reactions. It has been grown in swine and lamb kidney, bovine kidney, and other tissue cultures, and may be assayed by the plaque method.9 Neutralizing and complement-fixing antibody are formed by the infected animal, the former assayed by inoculation into the bovine tongue, and the antigen in the latter is infected epithelium of the tongue. The virus occurs as seven main serological types, three of which have a number of subtypes.

The disease may be reproduced in the guinea pig, usually by intradermal inoculation of the footpad. A vesicular eruption occurs at the site of inoculation, constitutional symptoms appear, and a secondary eruption appears on the tongue, gums, and lips. The eruption begins to subside about

two days after its appearance, and the lesions are healed in about two weeks. Infected animals are debilitated, but the disease is relatively mild in that the case fatality rate is 5 per cent or less.

The disease in cattle and other domestic animals is of considerable economic importance, not because of its fatality rate of 2 to 3 per cent, but because of its debilitating effect, with consequent loss in milk and meat production. Immunization has not been a satisfactory or practical control measure, and the disease is controlled by slaughter of infected animals and rigorous quarantine, the latter including certain meat products such as frozen beef in which the virus remains infective. The virus persists in dry form and may be transported mechanically on clothing, by wild birds, etc. Human infection appears to be very rare, and the disease is relatively mild and of minor significance in man except in relation to its spread among domestic animals. 136

Viral Diarrheas

Diarrheal disease of viral etiology occurs in both man and lower animals. ECHO virus type 18 has been found to be associated with summer diarrhea of infants.⁵⁹ Other epidemic diarrhea of the newborn may also be of viral etiology, and there is some evidence suggesting that the disease may be transmitted to calves, but the causative agent is poorly known.

Viral diarrhea, or epidemic nonbacterial gastroenteritis, occurs in adults also and has been studied at length by Gordon and his colleagues.67 It has been found that at least two kinds of disease occur, a febrile and an afebrile type. The afebrile type has an incubation period of two to three days and is characterized by nausea, vomiting, abdominal spasms, and watery stools, and an attack results in an immunity which persists for a year or more. It is associated with a filtrable agent, Marcy, which has been transferred through eight serial passages in human volunteers, but disease has not been produced in experimental animals. The agent associated with the febrile disease, which has a shorter incubation period and a less protracted course, has been designated FS, and there is evidence that this and the Marcy agent are immunologically distinct. The Marcy agent appears to be closely related to, if not identical with, the agent responsible for nonbacterial infectious diarrhea in Japan.⁶²

Diarrheal disease of viral etiology is not uncommon in lower animals. One of the most familiar of these to the laboratory worker is the epidemic diarrhea of suckling mice which occurs in explosive form, more commonly in the winter months. Intranuclear inclusion bodies are found in the epithelial cells of the villi, but the nature of the etiological agent is not well established. Calf pneumonia enteritis is of established viral etiology, the virus has been isolated, and the disease transmitted to susceptible newborn animals.25 The psittacosis agent may cause diarrheal disease in older animals, and three other immunologically distinct agents, presumably viral in nature, may also cause the disease. Transmissible gastroenteritis of swine is also of viral etiology, and the virus has been isolated and characterized immunologically. 69

Viral Hepatitis^{58, 104, 147}

Liver damage with icterus occurs in infectious diseases such as leptospirosis and yellow fever, but there is, in addition, hepatitis of specific viral etiology. There are two kinds of this disease, the one infectious hepatitis and the other serum hepatitis, which are caused by different viruses and differ in epidemiological character.

INFECTIOUS HEPATITIS

Infectious hepatitis (infective hepatitis, epidemic jaundice) is a subacute disease of world-wide distribution which tends to occur in children and young adults. It may appear in epidemic form within households and institutions and in military personnel, as in the two World Wars and the war in Korea. The prevalence of the infection is not precisely known, and it is probable that many cases are subclinical.

The incubation period varies from one to six weeks, with an average of perhaps three to four weeks. The disease is one of diffuse involvement of the liver and is separable into two stages, the pre-icteric and the icteric. The onset may be abrupt or insidious, and the symptoms include fever, gastrointestinal distress, headache, anorexia, and lassitude; the postcervical lymph nodes are often involved, and there is

leucopenia with relative lymphocytosis. This pre-icteric phase may persist for as long as three weeks but usually lasts for only a few days. Symptoms tend to subside, but there is exacerbation of some, especially those of abdominal discomfort, with the appearance of jaundice, and the liver and spleen are palpable and tender. Examination of biopsy specimens indicates progressive liver damage during the course of the disease, with relatively extensive parenchymal destruction by the time jaundice is apparent, but subsequently regeneration occurs which is complete in most cases by three months. Consistent with this, there is early evidence of hepatic dysfunction, and bilirubinuria occurs toward the end of the pre-icteric phase of the disease.

The icteric phase may persist for some weeks and is usually followed by uneventful convalescence. The case fatality rate is lower in children than in adults and has been reported at less than 2 per 1000 in military personnel. Relapse occurs with variable frequency, however, ranging from less than 1 per cent to as much as 18 per cent of cases. In many instances relapse is evident only as some degree of hepatic dysfunction, but in others the icteric phase of the disease recurs, although often in less severe form. In some few cases impairment of hepatic function may persist over protracted periods,

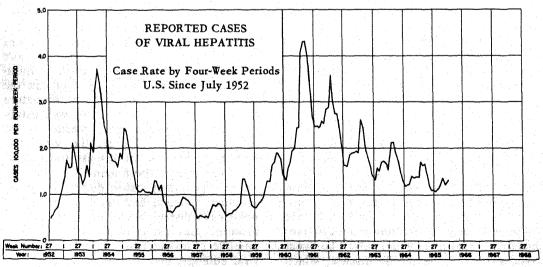

Figure 289. Cases of viral hepatitis, both serum and infectious, in the United States during the period 1952-1965. (Morbidity and Mortality Weekly Report, Annual Supplement, Vol. 14, No. 53. Communicable Disease Center, Public Health Service, U.S. Department of Health, Education, and Welfare.)

and in some small portion of these, symptoms may persist also. Rare complications of the disease include pneumonia, meningitis, and myelitis. A startling and provocative association between the prevalence of hepatitis and that of mongolism nine months later, with a periodicity of five to seven years, has been described in Australia; it has been suggested that subclinical infection of the aging mother at or on about the time of conception might affect the chromosomes of the ovum.¹⁸²

Hepatitis virus A. It is customary to designate the virus of infectious hepatitis as hepatitis virus A to distinguish it from the virus of serum hepatitis. It has not been possible as yet to infect experimental animals although there is evidence suggesting that chimpanzees may have been a source of human infection. 78, 146 There are a good many reports of isolation of a viral agent in embryonated eggs or one or another kind of tissue cell culture, 39, 50, 106, 109, 151 none of which has as yet been accepted as an etiological agent of the disease. 112, 115 Information is limited to that obtained from the inoculation of human volunteers.

The virus passes bacteria-proof filters such as the Seitz EK and is relatively resistant, for it is not inactivated at 56° C. for 30 minutes or by concentrations as high as 1 ppm of residual chlorine in the same time. It is present in the blood and feces in the pre-icteric or early icteric stages of the disease and has been found in the feces during the incubation period, as much as two to three weeks before the onset of jaundice,105 but attempts to demonstrate the virus in urine and in nasopharyngeal secretions have given equivocal or negative results. Man may be infected by either parenteral inoculation or ingestion of the virus, and it is probable that the latter route is involved in most naturally-occurring infections. 122, 141 Waterborne, milkborne, and foodborne epidemics have been described, and other more direct forms of contact are indicated by epidemiological evidence. The occurrence of the disease in the winter months suggests respiratory spread of the infection, but this is not consistent with transmission of the disease by biting insects even though the blood is highly infectious.

The relatively greater prevalence and severity of the disease in the lower age groups, including young adults, suggests that the infection may be relatively prevalent and produces an effective immunity. Pooled γ -globulin has a definite protective effect when given during the incubation period. Effective immunity has also been demonstrated experimentally with human volunteers, but there is some reason to believe that all strains of the virus are not immunologically identical although cross-protection occurs between strains. Hepatitis virus A is antigenically distinct from the virus of serum hepatitis. Second attacks of hepatitis occur, but the lack of a specific diagnostic test makes it difficult to assess their significance.

SERUM HEPATITIS

The disease serum hepatitis has probably been prevalent for many years, and possibly epidemics of jaundice associated with vaccination and the chemotherapy of syphilis were of this nature. It came into prominence in the early 1940's in connection with the immunization of military personnel to yellow fever with an immunizing agent which included human serum. Jaundice appeared to be associated with some, but not all, lots of serum, and with the elimination of serum from the vaccine, cases of so-called postvaccinal jaundice ceased to occur. Subsequently, there have been many instances of icteric disease following the injection of human serum or plasma, or blood transfusions, all indicating the presence of an infectious agent in human blood.

The incubation period of serum hepatitis is relatively long, eight to 22 weeks, and the disease is indistinguishable clinically from infectious hepatitis after the onset of symptoms. It has not been possible to transmit this disease to experimental animals, and information about the virus has been derived from experimental inoculation of human volunteers.

Hepatitis virus B. The causative virus is named hepatitis virus B to distinguish it from hepatitis virus A of infectious hepatitis. The two viruses have similar properties in that both show substantially the same resistance to heating, and activity persists in blood, serum, and plasma over extended periods. They are, however, immunologically distinct, there appears to be no crossimmunity between them, and they may be found together in both place and time. Hepatitis virus B is present in the blood, not only during the disease, but also in the

incubation period, and a chronic carrier state has been observed in which the blood may be infective for many months. It is not found in nasopharyngeal secretions, and it differs from hepatitis virus A in that it is not present in the feces, and man is not infected experimentally by the gastrointestinal route.

It is quite uncertain how the infection persists under natural conditions, but it is readily transmitted to man by inadequately sterilized syringes and needles used for purposes such as the administration of chemotherapeutic drugs, convalescent serum, or insulin, the withdrawing of blood, procedures such as tattooing, and the administration of infectious blood, plasma, or certain blood products such as fibrin foam and thrombin. Hepatitis virus A may also be transmitted in this way.

As in infectious hepatitis, antibody concentrates such as γ -globulin are prophylactic, and an attack of the disease appears to confer an appreciable degree of effective immunity. The virus is rarely found in γ -globulin; such preparations are possibly contaminated, but the virus may be neutralized by the relatively high concentration of antibody.

The persistence of the virus in blood, plasma, and serum poses a considerable practical problem in view of the lack of any method, other than human inoculation, of demonstrating its presence. It is destroyed by ultraviolet irradiation under experimental conditions, but this is not a practical method for the treatment of blood or plasma. and chemical sterilization, as by nitrogen mustards, has not yet been successful. Allen and his co-workers3 have found that the incidence of hepatitis in recipients of plasma is markedly reduced when the fluid plasma is allowed to stand at room temperature for three to six months, suggesting an appreciable degree of inactivation of the virus.

HEPATITIS OF LOWER ANIMALS

Hepatitis of viral etiology occurs in lower animals, including the dog and mouse, and a similar disease has been described in guinea pigs and ducks. 95 Murine hepatitis has been of interest as a disease possibly analogous to viral hepatitis of man.

Canine hepatitis. An infectious hepatitis of dogs was described in 1947 by Rubarth in

Sweden as caused by a virus related to the fox encephalitis virus; it is sometimes known as Rubarth's disease. The disease ranges in severity from symptomless infections to an acute fulminating fatal disease, with death occurring within 24 hours. The disease may be reproduced in susceptible puppies, but not in the usual experimental animals. Intranuclear inclusion bodies are found in the liver cells and vascular endothelium, and the virus passes bacteria-proof filters. The virus has been cultivated in the yolk sac of embryonated eggs and in raccoon kidney tissue culture, reproducing the disease in susceptible puppies after 12 passages in the former and after 39 passages in the latter. A lyophilized antigen prepared from infectious liver tissue fixes complement in the presence of serum from convalescent dogs, 111 and Rubarth found that the majority of adult dog serums contain complement-fixing antibody, suggesting that the infection is widespread and usually symptomless. This inference is substantiated by the isolation of the virus from dog kidney tissue cultures derived from two apparently healthy dogs.²¹

Human infection with the canine virus has been reported,¹⁷⁵ but there is apparently no relation between the human and canine viruses.¹² There is a one-sided antigenic relationship between certain adenoviruses and the canine hepatitis virus in that the latter will fix complement in the presence of antibody to the former, a relationship substantiated by the passive hemagglutination and gel-diffusion techniques.^{29, 63} The canine virus resembles the adenoviruses in being ether-resistant, producing similar CPE, and is of the same order of size.

Murine hepatitis.¹⁴⁰ Naturally occurring murine hepatitis was described in 1951 in England by Gledhill and Andrewes. The original disease was complicated by the presence of *Eperythrozoon coccoides*, but a fulminating infection, lethal in about 1 week, can be produced in the newborn mouse which is characterized by extensive degenerative lesions in the liver. The naturally occurring infection appears to be widespread among infant mice. ¹⁶² The adult mouse is not susceptible to the disease.

The virus is present in the blood, urine, and feces and is infectious by the gastro-intestinal as well as parenteral routes of inoculation. It has not been possible to obtain clear-cut evidence of growth of the virus in the embryonated egg. Inoculation with

relatively large doses of virus results in the appearance of an increased number of monocytes in the chorioallantoic fluid, an effect similar to that observed with human hepatitis virus, but the infection could not be passed in eggs. The virus multiplies in mouse macrophage cultures, but no CPE occurs and the presence of the virus is indicated only by comparative cell counts. More recently the MHV3 strain of the virus has been propagated serially in fetal mouse liver explants on rat-tail reconstituted collagen to produce cytopathic changes, largely in the epithelial outgrowth. ¹⁹¹ It has been found too that the MHV-(Babl D) strain multiplies

in mouse embryo cell cultures and, after passage, in mouse kidney epithelium and L cell culture, giving a cytopathic effect in all three systems. The NCTC 1469 clone of C3H mouse liver, maintained in chicken serum-containing medium, has been found to provide a sensitive assay system, by CPE and plaques, for recently isolated as well as adapted virus strains.

Complement-fixing and neutralizing antibodies have been found in considerable proportions of human serums, 3.5 per cent in children under nine and 21.8 per cent in adults,⁷⁵ suggesting a possible relationship between the human and murine viruses.

The Adenoviruses 26, 66, 179

The viruses known collectively as the adenoviruses were found in 1953, independently and almost simultaneously, by two groups of investigators. Rowe and his colleagues cultured tonsil and adenoid tissue fragments removed at operation as explants in plasma clots in roller tube culture. On continued incubation, a degenerative cytopathology was produced which was transmissible in series in various kinds of tissue cultures, including HeLa cell, fibroblast, and epithelial tissue cultures. The cytopathic changes included the development of acidophilic swollen nuclei which appeared to contain inclusion bodies. The viruses found apparently exist in the form of latent infections in human adenoid or tonsil tissue.

In attempting to isolate viruses associated with acute respiratory disease, diagnosed in part as primary atypical pneumonia, Hilleman and Werner cultured pharyngeal washings from affected individuals in HeLa cell culture. They isolated similar agents producing a degenerative cytopathology in tissue culture and showed that convalescent serums contained significant titers of complement-fixing antibody to the viruses isolated.

Subsequently, similar viruses have been isolated all over the world. They form a group containing a common complement-fixing soluble antigen but fall into distinct serotypes by cross-neutralization tests in tissue culture or by complement-fixation with antiserums prepared in the rabbit¹³³ (see below). This group of viruses was known first as the adenoid degenerative,

or AD, viruses. When their relation to some kinds of pharyngitis and conjunctivitis became clear, they were called the adenopharyngeal-conjunctival, or APC, viruses. Subsequently it was generally agreed that these names would be dropped, and these viruses are now designated the adenoviruses.

Morphology and growth. The adenoviruses are DNA viruses in which the nucleic acid occurs in double-stranded form. The virus particles are 70 to 80 m μ in diameter, and the capsid has cubic icosahedral symmetry and is icosahedral in form. There are 252 capsomeres and no enveloping membrane. These viruses are ether-resistant, stable to acidity, and heat sensitive.

They may be grown in a variety of cell cultures, of which the HeLa line is one of the most susceptible and widely used. They grow within the nucleus of the host cell, and the virus particles may occur in orderly arrays to give a crystalline-like appearance to the inclusion bodies. The CPE is characterized by a rounding and aggregation of the cells.

The human adenoviruses do not show hemadsorption, but some strains produce hemagglutinin and some RDE. They may be conveniently divided into four hemagglutinin (HA) groups on the basis of agglutination of rhesus and rat erythrocytes which parallel immunological groupings. HA group 1 agglutinates rhesus but not rat cells and does not produce RDE; HA group 2 agglutinates rat cells, some serotypes agglutinating rhesus cells to low titer, and produces RDE; HA group 3 gives incomplete

agglutination of rat cells and produces RDE; and HA group 4 does not agglutinate either rat or rhesus cells and does not produce RDE.

In addition to the human adenovirus types, these viruses are also found in lower animals, and occur as simian, bovine, canine, murine, and avian types. These do not appear to be pathogenic for man, nor are human types pathogenic for lower animals. Of these, one of the avian types, GAL (Gallus-adeno-like) has been frequently used for experimental purposes. The types found in lower animals, with the exception of GAL, often show unilateral serological cross-reactions with one or another of the human types.

Antigenic structure. At least two kinds of antigens are present in these viruses which may be analogous to those found in the influenza and related viruses. One is the soluble, complement-fixing antigen which is associated with a smaller particle size, 25 to 40 m μ , than that of the virus particle, and is separable from infectivity. This antigen is group-specific, and gives cross-reactions between the serotypes.

Serotypes within the group are differentiable by neutralization tests carried out in tissue culture, and at least some are also separable by complement fixation, using antiserums prepared in the rabbit by im-

munization with virus grown in tissue culture immunologically heterologous to that used in the preparation of complement-fixing antigens.¹⁵ A total of 28 differentiable serotypes have been described.¹⁵⁷ These types have been given Arabic numbers, and certain of them, types 3, 4, and 7, which have been examined in detail, have been

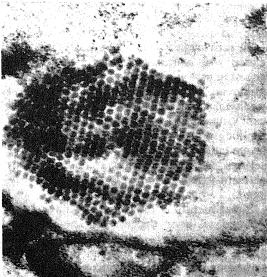

Figure 291. Electron micrographs of ultrathin sections of HeLa cells at 48 hours after infection with adenovirus type 4. Left, single particles and packed arrays of particles are distributed throughout the nucleus. Right, a higher magnification of a similar cell showing the single particles as spherical, ellipsoidal, or polygonal. (Touismis and Hilleman: Virology.)

found to be homogeneous even though the strains were widely different in temporal

and geographical origin.

Pathogenicity. 128, 184 As indicated above, adenoviruses were discovered both as latent infections⁶⁰ in normal persons and in association with respiratory disease. 16, 161 The disease produced by these viruses is an acute infection of the mucous membranes of the respiratory tract and of the eye, with involvement of the submucous lymphadenoid tissues of these areas, including the regional lymph nodes. While it is probable that many of them have the capacity to produce similar disease, there is a definite association of certain serotypes with clinical syndromes, and the evidence that the association is causal is, in some instances, substantially complete. 163 Other serotypes, although found in association with disease, have not been shown to be specific etiological agents. It has been of considerable interest, especially considering their ubiquity, that certain of the adenoviruses, human types, 7, 12, 18, and 31, have been found to be oncogenic in neonatal hamsters. 134

Acute respiratory disease. The adenovirus strains first isolated from military recruits with acute respiratory disease were type 4, and this serotype, together with types 3 and 7, has been found to be closely associated with the disease. The etiological relation of these serotypes to acute respiratory disease is indicated by a number of lines of evidence. In addition to repeated isolation from cases of such disease, rise in specific antibody titer occurs between paired serums from affected persons, and active immunization with polyvalent vaccine has been found to protect 50 to 70 per cent or better of nonimmunes exposed. Such vaccines have been prepared from formalininactivated virus grown in monkey kidney tissue culture. Further, serums from patients with acute respiratory disease, taken during World War II and stored in the interim, have been found to contain antibody to these serotypes, suggesting that the infection was prevalent at that time also. Type 14 has been found to be similarly associated with acute respiratory disease in the Netherlands.

Types 1, 2, and 5, as well as some others, have been recovered repeatedly from tonsils and adenoids removed surgically from persons not ill with respiratory disease, but these types have been found in association with febrile respiratory infections occurring for the most part in infants.

Pharyngoconjunctival fever. 13 This is a febrile disease characterized by pharyngitis and conjunctivitis which was defined as a clinical entity in connection with studies on adenoviruses. It occurs in epidemic form, largely in schoolchildren, and it is estimated that 50 per cent of nonimmunes exposed develop the disease. The conjunctivitis is usually unilateral, nonsuppurative, and does not

result in corneal damage.

It appears to be definitely established that adenovirus type 3 is the specific etiological agent of this disease. The virus has been repeatedly isolated from patients with this disease, both from the throat and from the involved conjunctiva, but not from healthy persons. A rise in specific antibody titer occurs during the disease, and the conjunctival disease has been reproduced in human volunteers by instillation of virus into the eve.

Epidemic keratoconjunctivitis. 180 This is a highly infectious disease characterized by relatively little ocular exudate, the development of round subepithelial opacities in association with the keratitis, and often swelling of the regional lymph nodes. There may also be systemic symptoms, especially headache. The incidence of complications resulting in impairment of vision has been variable. The disease appeared in this country in 1941 and 1942 in epidemic form in shipyard workers on the West Coast and is thought to have been imported from Hawaii.

Adenovirus type 8 has been isolated repeatedly from this condition in Japan, Italy, and Switzerland as well as in the United States. In one series of cases studied.91 62 per cent had neutralizing serum antibody titers of 1:40 or higher and 87 per cent 1:20 or higher, with peak titers as high as 1:160. A four-fold or greater rise in antibody titer between paired serums was found in 16 of 18 cases of the disease. The evidence strongly suggests that this serotype of adenovirus is the etiological agent of this disease.

Chapter Forty

THE ARBOVIRUSES (YELLOW FEVER, MOSQUITO-BORNE ENCEPHALITIDES, TICKBORNE ENCEPHALITIDES, DENGUE); THE LYMPHOCYTIC CHORIOMENINGITIS VIRUS

The arboviruses, or arthropod-borne viruses, occur primarily in reservoirs of infection in lower animals, including mammals and birds, and in arthropods. The last serve as vectors⁷⁰ to maintain the reservoirs of infection in vertebrates, and to transmit the infection to man, 102 but the human infection is often peripheral to the life history of the virus. 101, 146 These viruses multiply in the arthropod hosts to produce asymptomatic nonfatal infection, and in the case of ticks, but probably not mosquitoes, transovarian transmission of the infection occurs. While transmission to vertebrate hosts, including man, is by the infected mosquito or tick, the same virus is not transmitted by both kinds of arthropod. The great majority of these viruses are transmitted by mosquitoes, and a relatively smaller, and more homogeneous, group is tickborne.171

These viruses thus resemble certain of the rickettsiae, such as those of the spotted fevers, in having a vertebrate-invertebrate biological cycle, ¹⁰⁶ but differ from microorganisms such as the plague bacilli which produce a fatal infection in the insect vector, and from the agents of bacterial or virus infections, such as bacillary dysentery and rabbit myxomatosis, in which the infection is mechanically transmitted by the vector.

The grouping of these viruses as the arboviruses, or arborviruses, rests upon this epidemiological basis, and it is perhaps to be expected that the group includes viruses which appear to be unrelated in other respects.

Very many arthropod-borne viruses have been described, a number commonly given is 125, some having been found in association with disease but others in arthropods with or without serological evidence of vertebrate host infection and are of unknown pathogenicity. These viruses are found in various parts of the world, and many have been given place names of a somewhat exotic character. As a group they are not well known—present information concerning them is summarized by Mussgay¹⁰⁶—and generalizations as to their nature are based upon incomplete evidence.

They appear to be ether-sensitive, heat-labile (56° C.), acid-sensitive RNA viruses, at least some of which have cubic symmetry and probably single-stranded nucleic acid. The capsid is surrounded by an envelope, and most are 30 to 50 m μ in diameter, but some have been reported to be larger, 70 to 130 m μ . Many are cultivable in the chick embryo, in which a fatal infection is produced, and in various kinds of cell cultures. ⁶³

of which hamster kidney and chick embryo cells are the most generally useful. When CPE is produced, it is of a degenerative character, but may be incomplete and give rise to a carrier state. These viruses are pathogenic for the suckling mouse, and some for the adult mouse, producing encephalitis on intracerebral inoculation. In vertebrate hosts, the consequences of infection range from inapparent disease to systemic infection such as hemorrhagic fever with renal complications, yellow fever, and encephalitis which may be highly fatal.

Many of these viruses, though not all, are hemagglutinating for goose and neonatal chick cells. The specificity of the hemagglutinin-inhibiting (HI) antibody has been particularly useful in the immunological characterization of these viruses, allowing their separation into four groups designated A, B, C, and Bunyamwera, but leaving a

residuum of viruses which either do not form hemagglutinin, or whose hemagglutinin is antigenically related to few if any of the other known viruses. Of the established groups, group A includes the equine encephalitides, and group B includes yellow fever, Japanese B and St. Louis encephalitides, and the tickborne encephalitides. Further subdivision may be made on the basis of the specificity of complement-fixing and neutralizing antibodies, but there may be cross-reactions between members of different HI groups. Immunological characterization has, however, served to show the close relationship, or even substantial identity, of arboviruses found in widely separated geographical areas.

Here the more important and representative viruses will be considered individually, followed by a summary of their known interrelationships.

The Encephalitis and Related Viruses of Group A

The better known of the viruses of this group are those of the equine encephalitides and certain viruses found largely in Africa and producing dengue-like disease. There are a number of other viruses of this serological group which are not described here, including the Aura, Bebaru, Getah, Highlands I, Middleburg, Ndumu, Pixuna, Una, and Uruma viruses.

While "sleeping sickness," which may be of bacterial or protozoan etiology, has long been known to occur as sporadic cases and in epidemic form sometimes associated with other disease, the first encephalitis of probable viral etiology to be described with sufficient accuracy for tentative identification was encephalitis lethargica or von Economo's disease. This disease occurred in Roumania in 1915 and in France in 1916, was described by von Economo in Vienna in 1917, and apparently spread to this country in 1918. Epidemics occured in various parts of the world until 1926 but not thereafter. The disease was not of bacterial etiology, but no causative virus was isolated, and the disease has only an uncertain clinical identity. If it was a definite entity, it is not known why it failed to occur after 1926.

Study of the viral encephalitides began in the early 1930's with the isolation of a variety of viruses causing, or potentially capable of causing, encephalitis. The neurotropic character of some of these is marked, but in others it is latent, so that involvement of the central nervous system is relatively rare in the naturally-occurring disease and may be demonstrable only under experimental conditions as in the case of yellow fever virus. Certain of these viruses tend to form a group, related to some degree by antigenic character as well as by spread by arthropod vectors and their occurrence as natural infections of lower animals, and are set apart from other viruses, such as those of herpes simplex, mumps, and measles, and from the psittacosis group of organisms, all of which may at times infect the central nervous system.

EQUINE ENCEPHALITIS VIRUSES

Encephalitis of horses and mules occurring as summer epizootics in North America has been known for many years. ¹⁴¹ A virus was recovered by Meyer and his associates from the brains of horses during an epidemic of the disease in California in 1930 and was found in the blood and central nervous system of human cases of the disease by Howitt in 1938. A similar equine disease occurs in

the eastern part of the United States and Canada, and a virus was isolated from infected animals in 1933 by TenBroeck and Merrill during an epizootic occurring in the central Atlantic Coast states, and from the central nervous system of human cases of the disease in 1938 by Fothergill and his co-workers. A third kind of encephalitis of horses and mules occurs in the northern portion of South America, and is known as Venezuelan equine encephalitis. The causative virus was recovered from infected animals in 1938, laboratory infections in man were reported in 1943, and naturally occurring human disease in the following year. The three viruses are similar in many respects but are distinct antigenically and differ in other ways. The North American viruses have been intensively studied and are somewhat better known than the Venezuelan virus.

WESTERN EQUINE ENCEPHALITIS

The western equine encephalitis or WEE, virus is about 50 mu in diameter as indicated by sedimentation rates, although filtration experiments give a smaller value, 20 to 30 mu. Chemical analysis of purified preparations has shown about 50 per cent lipid, 4 per cent carbohydrate, and the remainder of the ribose type of nucleoprotein, and the virus appears to be a lipid-nucleoprotein complex. It is relatively stable to heat, for 10 minutes at 60° C., and to disinfectants such as ether, phenol, mercuric chloride, and phenyl mercuric borate, and is inactivated by 0.4 per cent formalin after two to four days. The last accounts for accidental infections which have occurred following the inoculation of formalin-inactivated experimental vaccines. It is readily cultivable in the embryonated egg and chick embryo by all routes of inoculation to produce a characteristically rapidly fatal infection of the embryo with generalized hemorrhage, thrombosis and necrosis, and death within 24 hours. It also grows in a variety of tissue cultures,9,75 and in both these and egg cultures large amounts of virus are produced.

The disease in man. The incubation period is from less than one to as long as three weeks, and the human disease varies from an almost symptomless or abortive form to an acute disease in which the patient be-

comes comatose within 24 hours. The disease is essentially a meningoencephalitis with rarely any involvement of the medulla or spinal cord. In the typical case the prodromal signs and symptoms may include headache, drowsiness, and fever. Symptoms of central nervous system involvement may also include tremor, convulsions, mental confusion, and amnesia, but paralysis is not common, occurring in perhaps 15 per cent of cases. The acute phase of the disease lasts seven to 10 days; recovery is usually uneventful and complete. In California in 1952, a peak year, 729 cases of encephalitis occurred, of which almost half were WEE infections, and the case fatality rate in that outbreak was 7 per cent. Serological evidence indicates, however, that many infections with this virus never result in clinical encephalitis, and many others are subclinical.

Experimental infections. The experimental animal of choice is the mouse, which may be infected by the intranasal, intraperitoneal, or intracerebral route. Following intraperitoneal inoculation, the virus appears in the blood, infects the nasal mucosa, and reaches the central nervous system via the olfactory nerves. Within a few days the animals show signs of meningoencephalitis. such as spastic muscular contractions and paralysis, followed by prostration and death, and the disease is similar to that in man. The infection of other animals, including rabbits, guinea pigs, and a number of birds, by the intracutaneous route results in an inapparent infection with viremia to give the kind of infection that probably occurs in animal reservoirs of the virus.

Immunity. Both complement-fixing and neutralizing antibodies are produced as a result of infection and are associated with a solid immunity. Antibody appears early in the infection, usually within a week of onset, and a rise in titer between paired serums is diagnostic. The complementfixing antibody usually disappears within a year, but the neutralizing antibody persists for longer periods and is the one titrated in serological surveys. Experimental animals may be immunized by the inoculation of formalin-inactivated mouse brain antigen, and in such animals the immunity to challenge inoculation is correlated with the titer of neutralizing antibody in the serum. Mice may be effectively protected against both intraperitoneal and intracerebral inoculation, but an abortive infection is produced

in the immunized guinea pig on intracerebral challenge. Mouse brain and chick embryo vaccines have not been particularly successful.⁹¹

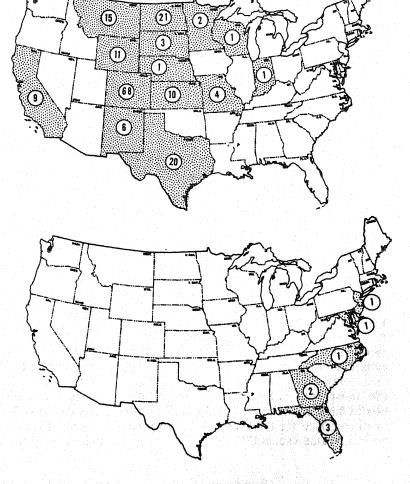

Naturally acquired infection is primarily an infection of wild birds which is transmitted by mosquitoes, and, in the natural history of the virus, infection of horses and man is incidental. The infection occurs west of the Mississippi River, but both serological evidence and isolation of the virus have shown that it is also present in some areas along the Atlantic coast, including New England, 60 and on the Gulf Coast.

Hosts. The virus has been recovered from about 20 species of wild birds and six species of mammals, and there is serological evidence of infection in more than 73 species of wild birds and most common domestic birds and mammals. ⁷⁹ It has been shown experimentally that the level of viremia is considerably higher in infected wild birds

than in domestic birds or mammals, and it may be inferred that mosquitoes may be more readily infected by feeding on the former. While this and other evidence leaves little doubt that wild birds are the important natural reservoir of infection, 115 and that infection in mammals and domestic birds does not play a significant part in the transmission cycle, it is not clear which species of wild birds are of primary importance and which are only secondary. It has been found also that garter snakes (Thamnophis sp.) may be infected, by inoculation or by infected C. tarsalis, the infection remaining latent during winter hibernation, and then becoming activated in the spring to levels of viremia sufficient to infect mosquitoes. 42, 153

Vectors. WEE virus has been isolated from 12 or more species of mosquitoes, from several species of bird mites, and from the assassin bug, Triatoma. Of these, it

Figure 292. The geographic distribution of western (top) and eastern (bottom) equine encephalitis as indicated by the number of cases reported in 1965. The numbers in circles are the numbers of cases reported in the indicated states. (Morbidity and Mortality Weekly Report, Annual Supplement, Vol. 14, No. 53. Communicable Disease Center, Public Health Service, U.S. Department of Health, Education, and Welfare.)

seems clear that Culex tarsalis is the primary vector of the infection, both in its natural transmission cycle and in the endemicity of the disease in man and horses in the western part of the country. The conclusion is based on detailed consideration of factors such as population density and blood-feeding habits as well as the consistent association of this mosquito with epidemics of the disease in mammals. WEE exists, however, in the absence of C. tarsalis, as in the endemic areas on the Atlantic and Gulf coasts, and has been isolated in those regions from species of Culex, Aedes, and Culiseta. These or other vectors are sufficient to maintain the infection at a relatively low endemic level, with transmission to both birds and mammals, but the relative unimportance of WEE in these areas is apparently due to the absence of an efficient vector such as C. tarsalis and possibly also to a degree of cross-immunity with the eastern virus which results in a lower level of viremia when WEE infection occurs in birds or mammals immune to the eastern virus.

EASTERN EQUINE ENCEPHALITIS

Eastern equine encephalitis, or EEE, is a disease similar to WEE but differing in its geographical distribution, arthropod vectors, and host range. It occurs in Atlantic and Gulf Coast states from New Hampshire to Texas and has been found as far west as Wisconsin in this country, in Canada, Mexico, the Caribbean area including parts of Central and South America, and in the Philippines.

The EEE virus is closely similar in size and chemical composition to the WEE virus and also produces rapidly fatal infections in the chick embryo as well as cytopathic changes in a variety of kinds of tissue cultures. Its pathogenicity for experimental animals parallels that of WEE virus, but it has a somewhat wider host range and is able to infect sheep, cats, and hedgehogs. A comparison⁹⁹ of tissue cultures and experimental animals has shown that chick embryo cells in culture are the most sensitive of the tissue cultures and that the suckling mouse is the most susceptible experimental animal host. Chick embryo cell culture of the virus has been used for the preparation of formalin-inactivated vaccine.91

Naturally acquired infection occurs in both horses and man. In the former the disease is substantially identical with that produced by WEE virus, but infections in man are relatively more severe and are characterized by a higher case fatality rate and a tendency to occur in children. A total of 50 human cases of the disease occurred in Massachusetts in small outbreaks in 1938, 1955, and 1956. On analysis³⁵ of these cases it was shown that 46 per cent of the affected individuals were less than three years old and 68 per cent under 10 years of age. Thirtyfour of the 50 cases were fatal, and recoveries were less satisfactory in younger survivors, with mental retardation, epilepsy, and paralysis of varying extent occurring as sequelae. Similarly, of 13 cases of the human disease which occurred in the Dominican Republic in 1948–1949, only one person was over eight years of age, and nine of the patients died.

Epidemiology.^{21, 64, 76} As in WEE, the natural reservoir of infection of EEE is in wild birds, with infection in mammals and domestic birds playing only a minor part in the natural transmission cycle. Infection of man and the horse is incidental and occurs during periods of high prevalence of the infection.

Hosts. A wide variety of wild birds, more than 40 species, have been found to show serological evidence of infection with EEE virus. In a general way, the smaller birds, including grackles, cardinals, and sparrows, show a higher level of viremia on experimental infection than do larger birds, such as herons and pheasants, and also tend to be more numerous. Further, the proportion of birds showing serum antibody is greater in migratory birds which winter south of the United States than in birds wintering in the north, suggesting a transmission cycle in Central or South America in birds found in this country in the summer.⁷⁸

There is evidence of fluctuation in the prevalence of the infection as indicated by the proportion of successful virus isolations and of birds showing the presence of serum antibody. During periods of low prevalence the incidence of virus isolations is less than 1 per cent and the incidence of antibody 15 to 20 per cent in caught wild birds, and the birds involved include the catbird, cardinal, hermit thrush, and yellow-crowned night heron. During periods of high prevalence

of infections, virus has been isolated from as much as 10 per cent of birds examined, and 50 per cent or more show the presence of antibody in the serum. At the same time the virus is found in additional species, such as the English sparrow and pigeon, and infection of horses and man may represent a similar spill-over of infection during periods of high prevalence.

It is of some interest that outbreaks of EEE have occurred on pheasant farms in Connecticut and in New Jersey. Presumably the infection is acquired initially from an arthropod vector, but direct bird-to-bird transmission occurs to give rise to epidemics of the disease. It is unlikely that caged pheasants play any significant part in the maintenance of the infection but may be considered as a sensitive indicator of the presence of the virus in the vicinity. 74, 92, 125

Vectors. EEE virus has been isolated from a number of species of mosquitoes. including Culiseta melanura, Mansonia perturbans, Anopheles crucians, Culex salinarius, Aedes mitchellae, and pooled Culicoides. C. melanura, in which the proportion of isolations has been relatively high, is a fresh-water swamp mosquito which bites birds freely. The distribution of this mosquito, and A. mitchellae and the saltmarsh species of Culicoides, coincides with the endemic areas of EEE virus infection. It is believed that C. melanura is one of the most important vectors in the maintenance of the natural transmission cycle but it seldom bites man or the horse, and it is probable that other vectors are involved. A. sollicitans, for example, has been found to be an excellent experimental vector, but C. pipiens is not. It is possible also that, with a high infection rate in the horse, mechanical horse-to-horse transmission may occur as a consequence of interrupted feeding of various biting insects such as stable flies, deer flies, and mosquitoes, for such mechanical transmission is demonstrable experimentally.

VENEZUELAN EQUINE ENCEPHALITIS¹³⁰

Venezuelan equine encephalitis, or VEE, occurred as an epizootic in horses and mules in Colombia in 1935, and the causative virus

was isolated during a similar epizootic in Venezuela in 1938. The disease has also been observed elsewhere in South America, *i.e.*, in Argentina, Ecuador, and Trinidad, and has been observed in Mexico¹²⁶ and Florida.²²

The infection in man usually results in a relatively mild, influenza-like disease with headache and fever, gastrointestinal disturbance, myalgia, and lethargy, with little or no indication of central nervous system involvement. Such cases occur as a result of naturally acquired infection, as in Colombia in 1952¹²⁴ and have occurred repeatedly as a result of laboratory infection. The disease lasts for three to five days, occasionally longer in more severe cases. Fatal cases are rare, and in two observed in Trinidad the onset was sudden with signs of encephalitis, followed by coma and death. On the other hand, serological evidence indicates that symptomless or subclinical infections in man may be relatively common in endemic areas. In man the virus is present in the blood and also in the nasopharynx, but there is no evidence of man-to-man transmission of the respiratory infection.

VEE virus infects horses and mules but not cattle. It is less pathologic for birds, and occasional birds, especially pigeons and doves, appear to be refractory to experimental infection. In contrast with WEE and EEE viruses, there is a high-level viremia in infected horses but only a low-level viremia in infected birds. It is probable that the reservoir of infection is mammalian rather than avian and that the disease is transmitted by an insect vector; *Mansonia titillans* transmits the infection under experimental conditions, but the vector of the naturally-occurring disease is not known.

Little is known also of the physical or chemical character of VEE virus, but it is immunologically distinct from WEE and EEE viruses. The usual laboratory animals are readily infected by peripheral inoculation, producing a high level of viremia and encephalitis, and the most useful experimental animals have been the mouse and the guinea pig. The virus grows profusely in the chick embryo and embryonated egg and is cultivable in tissue cultures of human uterus, HeLa cells, and guinea pig and hamster kidney cells.^{39, 75} Experimental animals may be immunized with formalin-inactivated chick embryo virus, and VEE vaccine has

been combined with WEE and EEE vaccines for the immunization of laboratory personnel. A variant, avirulent by other than the intracerebral route, which is an effective immunizing agent under experimental conditions has been described.61

SINDBIS VIRUS

This virus was isolated in 1955 from C. univittatus, and once from a hooded crow, in the Sindbis district in northern Egypt by the intracerebral inoculation of infant mice. It has also been found in India. 129 A number of animals may be infected experimentally. including chickens, horses, doves, and crows, to produce viremia without symptoms, but infant mice show paralysis and die in two or three days. The virus may be grown in the embryonated egg by inoculation of the yolk sac, and the embryos die in one to three days. It may also be grown in chicken embryonic tissue culture with marked cytopathic effects apparent in the fibroblast outgrowth, but no cytopathic effects are produced in HeLa cell or human embryonic skin-muscle tissue culture.38 The virus is 40 to 48 mu in diameter and thus intermediate in size in relation to the viruses described above. It is antigenically distinct.

CHIKUNGUNYA VIRUS

Chikungunya is a dengue-like disease which occurred as an outbreak of infection in the Newala district of Tanganyika in 1953. The disease in man appears to be a clinical variant of dengue in which the headache is lacking, but the eyeballs are tender and there are severe joint pains. In fact, this virus has been found, together with dengue viruses, in epidemics of dengue fever. In a study of the etiology of the disease, Ross¹¹⁹ isolated two viruses - the one Chikungunya virus, which is the etiological agent of the disease, and the other Makonde virus, named after the region (Makonde plateau) in which it was found-whose presence was fortuitous. The two viruses are immunologically unrelated. They also differ in their pathogenicity for the mouse in that the median incubation period of Chikungunya virus infection following intracerebral inoculation was four days, and nine days in the case of Makonde virus; the former killed in four to seven days while the latter required 14 days or longer.

The Chikungunya virus was isolated from the blood of patients with febrile disease and also from A. aegypti, and neutralizing antibody was found in the serum of convalescents. Rabbits and guinea pigs were apparently not susceptible to infection. Although it is a member of group A, this virus gives a slight cross-reaction in the neutralization test with dengue type 1, but not with type 2.

SEMLIKI-MAYARO VIRUS

SEMLIKI FOREST VIRUS

This virus was isolated in 1942 from A. abnormalis in the Semliki Forest of western Uganda by Smithburn and Haddow. 134 It is pathogenic for the mouse by peripheral as well as by intracerebral routes of inoculation and produces fatal infections in guinea pigs, rabbits, and rhesus monkeys on intracerebral inoculation. The brain lesions in infected animals are similar to those produced by the equine encephalomyelitis viruses. The embryonated egg may be infected by various routes of inoculation, including the chorioallantoic membrane, and the infection is uniformly fatal to the embryo. The titer of virus in the body of the embryo is as high as or higher than in the brain, generalized congestion and localized hemorrhages are found in both the brain and body, and the virus appears to be more pantropic than neurotropic in the embryo.

The virus is 30 to 40 m μ in diameter.^{23, 24} It is antigenically distinct and the Mayaro virus found in Trinidad is closely related to it. The Kumba virus, isolated from Eratmapodites mosquitoes in the Kumba region of the British Cameroons in West Africa has been found to be antigenically identical with it. While the Semliki and Kumba viruses have been found only in mosquitoes, the pathogenicity of the virus for man is shown by the occurrence of human disease in Trinidad and possibly elsewhere in South America, and it is apparent that the infection is widespread in the tropical regions of both continents.

MAYARO VIRUS

A febrile disease of viral etiology occurred as an outbreak in Mayaro county, Trinidad, and Casals and Whitman¹⁸ reported the isolation of the causative virus by intracerebral inoculation of sucking mice in 1957. The Mayaro virus is closely related to the Semliki Forest virus found earlier in Africa and, if not identical with it, is a closely related variant. An outbreak of febrile disease of apparently the same etiology occurred in the region of the Guama River in Brazil, and and surveys have shown that antibody to this virus, and the Semliki virus, is widely distributed in the Amazon region.

O'NYONG-NYONG VIRUS

This virus (ONN) was isolated from the blood of patients during a major epidemic of febrile dengue-like disease in Uganda and Kenya, and was also found in anopheline mosquitoes. It appears to be endemic in East Africa, and epidemics of illness occur from time to time. 167 Infected suckling mice show a patchy alopecia and retardation of growth, and mouse passage virus may be propagated in chick embryo fibroblast culture, forming plaques in monolayers. In the plaque-inhibition test the virus shows a one-sided relation to Chikungunya and Semliki Forest viruses.

The Mosquito-borne Viruses of Group B

Of the mosquito-borne viruses of group B, the classic and longest known is that of yellow fever. The viruses of Japanese B encephalitis, dengue fever, and St. Louis encephalitis are well-known and have been studied intensively, while still others are not so well known and/or have been described relatively recently. Some of the last, such as West Nile virus, produce mild disease or inapparent infection as indicated by serological surveys, and are widely distributed in certain areas. In addition to the viruses described here, this subgroup includes the Rio Bravo, Bussuquara, Modoc, Spondweni, Tembusu, and Usutu viruses and the mosquito-borne Wesselsbron virus.

ST. LOUIS ENCEPHALITIS

The disease known as St. Louis encephalitis, or SLE, was first observed in eastern Illinois in 1932 where it was diagnosed as von Economo's disease, and in the following year it occurred in epidemic form in and around St. Louis with an attack rate of 1 per 1000 and a case fatality rate averaging about 20 per cent. The infection occurs in the central states of the midwest and over the entire western half of this country, coinciding with WEE in the latter respect, and has been found in birds and mosquitoes in Trinidad. SLE, WEE, and EEE together

make up the most important arthropod-borne viral encephalitides in this country.

The SLE virus was isolated in 1933 by the intracerebral inoculation of monkeys. In many respects, including a size of 20 to 30 mu, it is closely similar to the WEE and EEE viruses described above, and other encephalitis viruses such as Japanese B encephalitis virus, but it is immunologically distinct and differs in its pathogenicity for various experimental animals. The virus is cultivable in chick embryo and mouse embryo tissue culture and in the volk sac or chorioallantoic membrane of the embryonated egg. Pocks are not produced on the chorioallantoic membrane, but the infected membrane is edematous, with evidence of cell proliferation and focal necrosis. In contrast to the WEE and EEE viruses, SLE virus infection of the embryonated egg does not result in rapid death of the embryo.

The susceptibility of rhesus monkeys to intracerebral inoculation is somewhat irregular, only some strains producing an infection, and the virus tends to be lost on passage; the Cebus monkey appears to be refractory to infection. Infant mice are the most susceptible of the usual experimental animals and may be infected by all routes of inoculation, and adult mice may be infected by intracerebral or intranasal inoculation. Only an inapparent infection is produced in rabbits, guinea pigs, and various birds, and

adult rats, sheep, and ferrets are refractory to infection.

The disease in man. The disease in man is closely similar to WEE, ranging in severity from an abortive type of infection with headache and fever to a severe disease with abrupt onset and symptoms including abdominal and muscular pain, sore throat, conjunctivitis, and signs of neurological disturbance such as ataxia, mental confusion, and occasionally a spastic type of paralysis. The incidence of the disease is relatively high in infants, least in older children, and rises again in the higher age groups. The fulminating type of disease tends to occur in infants, and in a considerable portion, 10 to 40 per cent, of recovered cases there may be evidence of damage to the central nervous system such as mental retardation and hydrocephalus. Recovery in the older groups is usually complete, with sequelae in 5 per cent or less of survivors, but the case fatality rate rises with age, and recovery is often protracted, to several months in severe cases. There is evidence which suggests that inapparent infection may be common.8

Complement-fixing and neutralizing antibodies appear in the serum by the end of the first week of the disease, and a rise in titer between paired serums is diagnostic. Neutralizing antibody, titrated in the mouse, persists for long periods, possibly for life, but complement-fixing antibody declines to insignificant levels within two to three years.

Epidemiology.^{21, 64, 76} Unlike WEE, which occurs in the summer, SLE tends to occur in late summer and early fall. Following an outbreak in St. Louis in 1937, the disease appeared in sporadic form for several years, small urban and suburban outbreaks have occurred since 1954, and an epidemic of over 100 cases occurred in Louisville, Kentucky, in 1956, and one of a similar magnitude in St. Petersburg, Florida, in 1962.⁷

Hosts. The reservoir of SLE virus infection, like that of WEE and EEE, is in birds, and the disease is transmitted by mosquitoes. The virus has been recovered from several species of birds, and serological evidence of infection has been found in 55 species of wild birds and a number of mammals, as well as in most domestic birds and mammals examined. The level of viremia is relatively low, but mosquitoes seem to be more readily infected with this virus than with others in which a high level of viremia is required for infection of the vector. The more important vertebrate hosts appear to be the small perching birds, such as finches and sparrows. and there is also reason to believe that chickens are important epidemic hosts for the virus.

Vectors. SLE contrasts with WEE with respect to arthropod vectors in that the mosquito susceptibility range tends to be

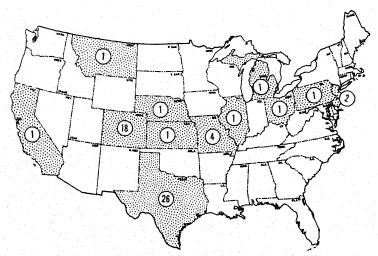

Figure 293. The geographic distribution of St. Louis encephalitis as indicated by the number of cases reported in 1965. The numbers in circles are the numbers of cases reported in the indicated states. (Morbidity and Mortality Weekly Report, Annual Supplement, Vol. 14, No. 53. Communicable Disease Center, Public Health Service, U.S. Department of Health, Education, and Welfare.)

reversed. WEE and EEE readily infect species of Aedes and Psorophora, but not Culex except C. tarsalis, while SLE is highly infectious for species of Culex but develops poorly in Aedes and Psorophora. These differences are reflected in the epidemiological pattern of the disease, and SLE occurs in two forms, the urban and rural types. The former, in which the disease is found in populated areas of the Midwest where C. tarsalis is scarce or absent, is transmitted to man by mosquitoes of the C. pipiens complex, including C. pipiens. C. quinquefasciatus, C. molestus, and possibly others. In western and rural areas, however, the primary vector appears to be C. tarsalis.

In the rural type of disease in the West, the transmission cycle includes wild, and possibly also domestic, birds as reservoirs of infection, maintained by transmission of the virus by *C. tarsalis*, with occasional infections occurring in man. In more densely populated areas in which *C. tarsalis* is seldom present, the infection is presumably introduced by wild birds and transmitted to local wild and domestic birds, and also to men, primarily by *C. pipiens* and *C. quinquefasciatus*, and outbreaks of the disease in man are associated with relatively dense populations of these mosquitoes.

JAPANESE B ENCEPHALITIS163

Encephalitis of viral etiology occurs with some frequency in various parts of the Far East, and a related form of viral encephalitis has been found in Australia. A closely similar virus appears to be widespread in Africa associated with febrile disease but usually not with symptoms of encephalitis. These viruses are related to SLE and yellow fever viruses on the one hand, and to the Russian spring-summer encephalitis and related viruses on the other.

Encephalitis has occurred in Japan in the late summer for many years and has assumed epidemic form from time to time. The disease has been called Japanese B encephalitis, or JBE, to distinguish it from von Economo's disease which was called Japanese A encephalitis in Japan. An epidemic of over 6000 cases with a 60 per cent case fatality rate occurred in 1924, and out-

breaks occurred every summer to give, in the period 1924 to 1940, a total of approximately 27,000 cases of acute encephalitis. The infection has been found in many parts of the Far East, including China, Russia, Formosa, Thailand, Burma, Malaya, India, the Philippines, and portions of Indonesia, and an epidemic of more than 5500 cases with a 50 per cent case fatality rate occurred in Korea in 1949. Isolation of the virus was reported in 1936 by Japanese workers, Kasahara and his colleagues, and Taniguchi and his colleagues.

The virus is similar to those of the equine encephalitides and SLE in size and properties but has a relatively wider range of pathogenicity for experimental animals. The mouse, monkey, hamster, and young rat are susceptible in that order, the guinea pig is relatively resistant, and rabbits and chickens respond with viremia. Domestic animals, such as the horse, cow, sheep, and goat, may be infected experimentally and show serological evidence of naturally occurring infection in endemic areas, and epidemics of encephalitic disease in horses are often associated with epidemics of the disease in man. In the rhesus monkey an acute encephalomyelitis with relevant symptoms which simulates the human disease is produced following intracerebral or intranasal inoculation, and, in contrast with SLE virus, the infection may be carried in monkey passage. The virus is cultivable in the chick embryo and on the chorioallantoic membrane of the embryonated egg with death of the embryo within 72 hours. It will also grow on a variety of tissue cultures. 6, 83, 116

The disease in man. The disease occurs in man as a symptomless or subclinical infection,52,69 an abortive type of disease in which fever and fleeting signs of central nervous system involvement occur, and as acute meningoencephalomyelitis. In the last there is extensive cortical damage with focal perivascular infiltration, ganglion cell degeneration, and destruction of the Purkinje cells of the cerebellum, and there are lesions in the cord simulating those of poliomyelitis. The onset may be abrupt or insidious, and is characterized by fever, nausea, and disorientation. In the severe disease the neurological symptoms are marked, and include spinal rigidity, tremors, convulsions, and spasticity. The acute phase of the disease may last as long as two weeks, but recovery

is usually complete, and sequelae such as neurological or psychotic changes occur in less than 10 per cent of survivors.

The immune response is evident as the appearance of complement-fixing and neutralizing antibodies in the serum and occurs within one to two weeks after onset of the disease. The neutralizing antibody persists for a long time, and the associated immunity to the disease is thought to be relatively permanent. Complement-fixing antibody may appear in immunes following inoculation of vaccine that will not induce the formation of this antibody to significant titer in the normal individual. A formalin-inactivated chick embryo vaccine has been used for human immunization with suggestive results. 156 Another approach is that of primary inoculation with heterologous but related living virus, the West Nile virus (see below), followed by inoculation with inactivated vaccine of other viruses such as that of JBE.71

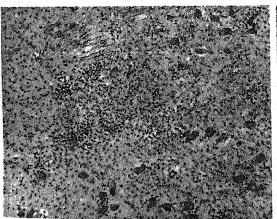

Epidemiology. Natural infection of mammalian hosts other than man with the virus occurs, as indicated by extensive outbreaks among horses and an infection of swine which results in abortion, stillbirth, or affected young, and other domestic animals show serological evidence of infection. Bats may be infected experimentally to give a mosquito-bat-mosquito cycle, but its occurrence in nature is not known. Serum antibody has also been found in a number of

species of Japanese birds, suggesting that there may be avian as well as mammalian reservoirs of infection.⁵⁷

A number of species of culicine mosquitoes, including *C. tritaeniorhynchus* and *C. pipiens* var. pallens, can be infected with the virus, and can transmit the infection under experimental conditions. *C. tritaeniorhynchus* has been found to be naturally infected in Japan, and this and other evidence suggests that this mosquito may be one of the principal vectors of the disease there.⁵⁸

MURRAY VALLEY ENCEPHALITIS

Encephalitis of viral etiology has occurred in Australia from time to time, and the virus appears to be a varient of the JBE virus. Epidemics of acute encephalitis occurred during the summer months between 1917 and 1926, in the first of which the disease occurred largely in small children, with a case fatality rate of 70 per cent, but subsequent epidemics were not as severe. In the severe form the disease was fulminating and resembled JBE in both symptoms and pathology. A virus was isolated from the central nervous system by inoculation of monkeys but unfortunately was lost before its characteristics could be determined, and the disease was called Australian X disease. It has not recurred since 1926.

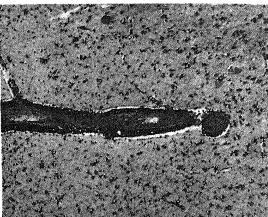

Figure 294. Pathological changes resulting from Japanese encephalitis infection. Left, substantia nigra from a human case; foci of mononuclear cell infiltration are present, and numerous ganglion cells are in a disintegrated state or have disappeared. Hematoxylin and eosin; \times 90. Right, region of superior temporal gyrus from a human case; a vein at the corticomedullary junction is surrounded by a "cuff" of lymphocytes. (Haymaker and Sabin: Arch. Neurol. Psychiat.)

DENGUE 953

In the summer of 1950–1951 an epidemic of encephalitis occurred in the Murray Valley in Victoria, Australia, in which 40 cases were recognized and 17 of these were fatal. A few cases occurred in 1956, and the disease seems to appear only sporadically. It has also been observed in New Guinea, where serological surveys have suggested a patchy distribution of the infection. The disease is called Murray Valley encephalitis, but there is reason to believe that it represents a recrudescence of Australian X disease.

A virus was isolated on the chorioallantoic membrane of the embryonated egg, killing the embryo in two to three days, and adapted to infant mice in which it produced encephalitis, fatal in about a week, on intracerebral inoculation. The virus was found to be closely similar to, but not immunologically identical with, JBE virus.^{1, 133}

Complement-fixing and neutralizing antibodies, the latter demonstrable in the mouse, are produced in response to infection, and surveys in the epidemic area showed that about 5 per cent of persons with no history of the disease had significant titers of complement-fixing antibody. It was found in further studies that antibody is relatively widely distributed throughout eastern Australia, not only in man, but also in horses and a number of species of wild birds. 103 There is circumstantial evidence which suggests that C. annulirostris transmits the disease.96 The disease may, like SLE and the equine encephalitides, exist in a reservoir of infection in wild birds, maintained by mosquito and possibly bird mite transmission. It is transmitted to man and other mammals by mosquitoes.

WEST NILE VIRUS

The isolation of this virus from a native of Uganda with a mild febrile illness was reported by Smithburn in 1940; it was subsequently isolated in Egypt in 1951;¹⁰⁰ and outbreaks of the disease caused by it have been observed in Israel.^{46, 95} In contrast to JBE, the disease is rarely fatal and usually does not take the form of encephalitis. The incubation period of the disease in Israel was two to six days, and it was characterized by an abrupt onset, fever, drowsiness, and

severe frontal headache. A maculopapular rash may develop, more commonly in children, there may be abdominal pain with anorexia and nausea, and there is a general enlargement of the lymph nodes. The acute phase of the disease persists for less than a week, but convalescence may be protracted.

The virus is closely similar to the JBE virus, being of the same order of size and immunologically related to it and to SLE virus. It has been of particular interest in connection with active immunization to infection with closely related viruses such as JBE virus and others. Mice may be infected by the intracerebral route, and the infection is characterized by degenerative changes in the Purkinje cells of the cerebellum in both these animals and in monkeys. The virus grows on the chorioallantoic membrane of the embryonated egg and in a number of kinds of tissue cultures.

Serological evidence indicates that the infection is widespread in Africa, probably as inapparent infections, not only in Uganda and Egypt, but also in South Africa, the Republic of the Congo, and the Sudan. As many as 70 per cent of persons examined in Egypt show significant antibody titer, and the disease has been studied extensively there. The disease occurs largely during the summer and is sporadic rather than epidemic in form. The occurrence of outbreaks of the disease in Israel in 1951 and 1954 may have been due in part to relatively recent introduction of the virus.

The virus has been isolated from birds, pigeons, and the hooded crow in Egypt, and there may be an avian reservoir of infection. Virus has also been found in *C. univittatus* and *C. antennatus*, and *C. pipiens* and *A. aegypti* transmit the disease experimentally. *C. univittatus* is regarded as the most probable important vector of the infection.

DENGUE¹²²

Dengue, or breakbone fever, is an infectious disease transmitted by mosquitoes which is endemic, and sometimes epidemic, in tropical and subtropical climates; it may occasionally occur in temperate zones. Epidemics may be very large; it is estimated

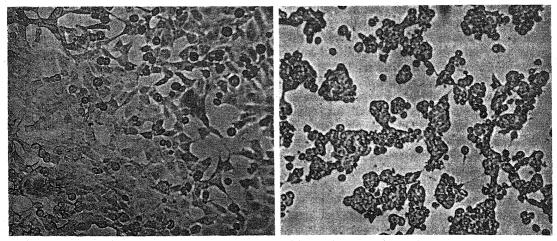

Figure 295. The CPE produced by West Nile virus in HeLa cell culture. Left, uninoculated cell culture; right, four days after inoculation with virus.

that there were between one and two million cases of the disease in the southern states in this country in the epidemic of 1922, more than a million cases occurred in Greece in 1927–1928, and a greater number in Japanese port cities from 1942 to 1945, with one-third to one-half the population of Osaka affected in 1944. It was first studied in the Philippines by medical officers of the United States Army, who established the viral nature of the etiological agent and its transmission by A. aegypti.

Dengue also occurs in a more serious form as a kind of hemorrhagic fever which has occurred in epidemic form in the Philippines and in various parts of southeast Asia, as in Singapore, Thailand, and Vietnam.

Dengue viruses. The virus is similar in size to the yellow fever and encephalitis viruses described above, possibly slightly smaller, and its size is usually given as 12 to 25 m μ . In electron micrographs dumbbell-shaped particles are observed, but it is not established that these represent virus particles. In the 1950's serotypes were differentiated, first types 1 and 2, which are by now the best known, and subsequently types 3 and 4, which were found in studies on hemorrhagic fever; there may be two additional serotypes, types 5 and 6.

On primary isolation the dengue virus does not produce CPE in monkey kidney cell cultures, but growth is inferred from resistance, increasing with passage, to superinfection with poliovirus, *i.e.*, interference. Following adaptation, usually by intracerebral passage in the mouse, the virus grows with CPE and plaque formation in monkey

kidney tissue cultures,⁴⁵ and mouse-adapted virus may be propagated serially in HeLa cells with CPE¹⁰ and production of hemagglutinin.¹¹ The serotypes are differentiated by neutralizing and complement-fixing antibodies and by HI, and seem to be more closely related to one another than to other members of group B by the last criterion.

Pathogenicity for lower animals. Various monkeys, including species of Cynomolgus, Ceropithecus, and Macacus, and chimpanzees may be infected with the production of antibody, but the infections are symptomless, and even inapparent infections are not produced in the usual experimental animals. Newborn mice, however, may be infected by intracerebral inoculation, with the development of immunity but no symptoms, or minor symptoms, of disease on primary isolation.

On passage the virus may become adapted to mice, giving high titers of virus in the brain, producing motor disturbance and partial flaccid paralysis with or without signs of encephalitis. Adult mice may be infected by intracerebral inoculation of well-adapted strains but are refractory to other routes of inoculation. A number of strains of both types of the virus have been so adapted to mice. Adapted virus may produce fatal paralytic disease in rhesus monkeys, simulating experimental poliomyelitis, following intracerebral inoculation. In general, there is no satisfactory experimental animal host for unmodified virus, and infection experiments have been carried out with human volunteers.

Dengue fever. Experimental studies

have shown that, following intracutaneous inoculation of as little as 10 minimal infecting doses (MID) for man, local erythema and edema develop in three to five days which are associated with local multiplication of the virus. Sabin has used this reaction for immunological studies for, when virus is mixed with appropriate amounts of antiserum prior to inoculation, the reaction does not occur. With the onset of fever, the blood may contain as much as one million MID per ml.

The incubation period is usually five to eight days. The prodromal symptoms include headache, backache, and malaise, followed in six to 12 hours by an abrupt rise in temperature. The acute phase of the disease is characterized by headache, the severe pain in the muscles and joints which has led to the name breakbone fever, abdominal pain, constipation, and anorexia. A maculopapular eruption occurs with variable frequency which appears about the third day of the disease, spreading from the trunk to the extremities and face, and persists for three to four days. The febrile period lasts for five or six days and commonly terminates by crisis. The disease is seldom if ever fatal.

Hemorrhagic fever.⁵¹ The occurrence of disease characterized by severe hemorrhage or shock with 10 to 15 per cent mortality has been known in association with dengue fever epidemics since the turn of the century. The dengue virus etiology of this form of the disease was first recognized in the Philippines in 1956.55 Subsequently it has occurred in epidemic form in Thailand, 53, 56 Malaysia,90 and Vietnam.54 From 1961 to 1965 more than 16.000 cases have occurred in children in Thailand with about 1000 deaths; because of its presence there it is also known as Thai hemorrhagic fever. This kind of disease occurs most frequently in children under 12, and is characterized by capillary damage, visceral lesions especially in the liver, petechiae, blood in vomitus and stools, and shock. It may be associated with any of the serotypes of the virus, and there is epidemiological evidence suggesting that some strains may be more virulent than others.

Other hemorrhagic fevers. Hemorrhagic fever occurring in the Western Hemisphere, in South and Central America, ¹⁴⁸ is of different viral etiology. A virus, designated Junin virus, ¹¹³ was isolated in Argentina during an epidemic in 1958. Hemorrhagic

fever occurred in Bolivia,93 first in 1959, and the viruses isolated were found to be indistinguishable from the Junin virus by complement fixation, but distinct by the neutralization test. The prototype strain of this group is the Carvallo strain, and the viruses as a group are designated the Machupo virus.⁷³ Both have been found in small rodents and. in the case of Junin virus, in mites, but there seems to be no evidence of arthropod transmission of the Bolivian viruses. These are, nevertheless, considered to be arboviruses, but are ungrouped since they are unrelated serologically to the HI groups. Another immunologically related virus, Tacaribe virus, has been isolated from bats in Trinidad, but is not known to be associated with disease in other forms.32

Still another kind of hemorrhagic fever was recognized in Manchuria in 1939 by Japanese workers, and appeared among United Nations military personnel in 1951 in Korea, where approximately 1000 cases of the disease occurred. It was shown by both Japanese and Russian workers that the disease could be transmitted to human volunteers by the parenteral inoculation of blood or urine taken early in the febrile period of the disease, that the causative agent passed bacteria-proof filters, and that convalescent serum is protective. While this evidence is taken to indicate that the disease is of viral etiology, it has not been possible to produce infections in experimental animals nor to culture a virus by the usual methods, and the etiology remains somewhat obscure. The epidemiological character of the disease is consistent with that of an arthropod-borne infection existing as an animal, possibly rodent, reservoir of infection, a conclusion reached by Japanese, Russian, and American workers. 41, 131, 144 This kind of hemorrhagic fever is more widespread than had been originally supposed and occurs across northern Asia and Europe from Korea to Scandinavia.25 It is not to be confused with Crimean or Omsk hemorrhagic fevers, which are tickborne.

Immunity. Recovery from dengue either in man or in those experimental animals which can be infected with the virus, results in a solid immunity and the appearance of complement-fixing and neutralizing antibodies in the serum. Complement-fixing antigen may be prepared from mouse brain, and protective and neutralizing antibodies are demonstrable by challenge of immunes

in the first instance, and by the neutralization test using the skin reaction in man noted above, or in mice, in the second.

The solid immunity is to the homologous serotype and has been shown experimentally to persist for at least 18 months. Convalescents have a considerable degree of initial immunity to the heterologous serotype of virus, but it disappears relatively rapidly. Thus, within two months after recovery, the heterologous immunity probably often suffices to prevent naturally acquired infection. It deteriorates thereafter so that infection between two and nine months after recovery with the heterologous serotype results in a modified form of the disease which is of shorter duration, without rash, and generally less severe. Active immunization with mouse-adapted strains of the virus has given encouraging results. 123, 127

Epidemiology. The animal reservoir of dengue virus appears to be man and various species of monkeys in which viremia occurs even though the infection is symptomless; birds do not seem to be infected. The virus is transmitted by the domestic mosquito, A. aegypti, as noted earlier, and also by A. albopictus, which can exist in the bush or jungle and transmit the infection among primate hosts other than man. Epidemiological observations suggest that A. scutellaris and A. polynesiensis may also be vectors under natural conditions. It may be noted that A. vexans, A. taeniorhynchus, C. pipiens, and anopheline mosquitoes such as Anoph, quadrimaculatus and Anoph. punctipennis are apparently unable to transmit the infection.

Man is infective for the mosquito: i.e., there is viremia, for a period including the last day of the incubation period and three days or more after onset of the disease, and presumably monkeys are similarly infective since viremia is demonstrable experimentally for five to eight days after infection. The extrinsic incubation period is 10 days to two weeks, and the mosquito remains infectious for life, but there is no congenital transmission of the virus. Endemic persistence of the infection depends upon climatic conditions such that mosquitoes may survive throughout the year, together with a sufficient number of newborn mammalian host susceptibles to maintain the transmission cycle.

NTAYA VIRUS

This virus was isolated135 in 1943 from pooled mosquitoes of several genera and species, including Culex and Aedes, collected in the Ntava swamp in western Uganda. The infection was uniformly fatal to mice by intracerebral inoculation after the eleventh passage, but the intranasal and intraperitoneal routes of inoculation were not effective. Infections uniformly fatal to the embryo are produced by inoculation of the volk or amnionic sacs, but embryos die only irregularly following inoculation on the chorioallantoic membrane or allantoic cavity. The virus is neurotropic in the embryo, with higher concentration of the virus in the brain than in other parts of the body. and the gross hemorrhagic lesions are confined to the brain. The virus is 70 to 120 m μ in diameter and antigenically distinct but has been found to give some cross-reaction with Ilheus virus in the complement-fixation reaction. There is no evidence of naturally occurring mammalian infection, and persons living in the vicinity of the swamp did not show serum antibody.

UGANDA S VIRUS

The Uganda S virus was isolated in 1947. in Bwamba county, Uganda, from a pool of mosquitoes containing A. longipalis, A. ingrami, and A. natronius, by intracerebral inoculation in the mouse.29 Hamsters may be infected by the intracerebral route, but the infection is not uniformly fatal. The virus may be grown in the embryonated egg by yolk sac and amnionic sac inoculation, reaching higher concentrations in the brain than in the body of the embryo. The embryos are usually not killed, and the gross lesions are minor, consisting of congestion and some small hemorrhages in the brain. The virus is 15 to 30 m μ in diameter, and antigenically distinct, but gives irregular cross-reactions in the complement-fixation test with some yellow fever virus antigens. Neutralizing antibody has been found in human serums, with 7.7 per cent positives found in Uganda and Tanganyika, and 35 to 50 per cent in Nigeria. On this basis, the virus would seem to be one of the most common in Nigeria. CONTRACTOR OF THE STATE OF THE STATE OF

TO BE WINDOWS TO SERVER STORY

ZIKA VIRUS

This virus was isolated in 1947 and 1948. first from the blood of a captive monkey (vellow fever sentinal) in the canopy of the forest near Zika, Entebbe, Uganda, and again from a pool of A. africanus in the same region.30 It was isolated in mice by intracerebral inoculation but is not pathogenic for hamsters or for mice by the intraperitoneal route. It is cultivable in the embryonated egg by inoculation into the volk. amnionic, and allantoic sacs but usually does not kill the embryo: gross lesions are uncommon, and the virus is pantropic rather than neurotropic in the embryo. The virus is 15 to 30 mu in diameter and antigenically distinct.

ILHEUS VIRUS

The Ilheus virus was isolated in 1947 in Brazil by Laemmert and Hughes⁸¹ from pooled Aedes and Psorophora mosquitoes. It is also found in Panama, where birds may be hosts.⁴⁰ It is cultivable on the chorioallantoic membrane of the embryonated egg but disappears from this site relatively rapidly. The embryo is infected following yolk sac inoculation, and the virus is found in highest concentration in the brain. It is highly pathogenic for mice, even when inoculated by other than the intracerebral route. It is 15 to 30 m μ in diameter.

YELLOW FEVER¹⁴³

Yellow fever is an acute disease, occurring in epidemic and endemic form, which was first observed in Central America in the middle of the seventeenth century. It is uncertain whether the original focus of infection was in Africa or the Western Hemisphere, but in the eighteenth and nineteenth centuries the disease was widely distributed in the Caribbean area, including the adjoining coasts of North, Central, and South America. It occurred in epidemic form in more northern cities in this country, including Philadelphia, New York, and Baltimore, and it is estimated that there were at least half a million cases of the disease in this country in the nineteenth century. It occurred in epidemic form in Spain in 1800 with 60,000 deaths and in Rio de Janeiro with more than 20,000 deaths between 1851 and 1883, and there were almost 36,000 deaths from the disease in Havana during the same period.

The occurrence of the disease in American military personnel during the Spanish-American war resulted in the classic studies of the Yellow Fever Commission of the United States Army under Dr. Walter Reed at the beginning of the twentieth century, with evidence of mosquito transmission and the viral nature of the infectious agent. Later work appeared to suggest that the disease is a leptospirosis, but in the late 1920's its viral etiology was firmly established.

The virus, shown to be filtrable by the work of the Commission, is one of the smaller viruses, with a diameter of 30 m μ , and it is readily filtrable through the usual bacteriaproof filters. It is relatively labile, is readily inactivated by heating and by the usual disinfectants, but is preserved in 50 per cent glycerol and in lyophilized form.

The disease in man. The disease is transmitted to man by the bite of infected mosquitoes, and the incubation period was found to be one to three days in early experimental infections. The onset is sudden with headache, backache, and rigor, and the temperature rises rapidly to reach a maximum within 48 hours. In the first, or congestive, stage of the disease there is nausea and vomiting, the face is flushed, and a tendency to hemorrhage becomes apparent. After three or four days the temperature falls, then rises again, and the second stage of the disease is characterized by venous stasis and a marked tendency to hemorrhage; prostration occurs, jaundice appears but is not marked, and the kidneys are involved and there is albuminuria. Death occurs by the sixth or seventh day, seldom after the tenth day, or recovery is rapid and uneventful. Many infections are mild or almost symptomless. and the fatality rate is not known with precision; it is estimated to be about 5 per cent.

The disease is one of the hematopoietic system, there is little inflammatory reaction, and the tissue changes are degenerative in nature. These occur in the liver, kidney, and heart, and there is evidence of hemorrhage. The characteristic, and pathognomonic, lesion is a hyaline type of necrosis in the

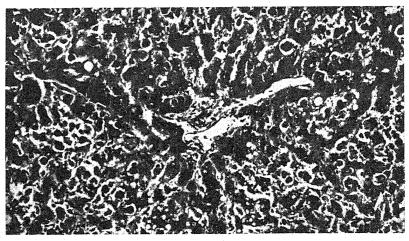

Figure 296. Section of liver from a human case of yellow fever. Midzonal necrosis is apparent. Hematoxylin and eosin; reduced from x 235. (Theiler.)

midzone of the liver, and the affected cells are known as Councilman bodies. Fatty degeneration occurs in the kidney tubules but is not distinctive, the spleen is hyperemic and shows degenerative changes, and degenerative changes are found in the heart.

Experimental infections. The human disease is closely reproduced in the rhesus monkey,4 and a number of species of monkeys are susceptible to yellow fever; in fact, natural infection appears to be widespread among primates in certain areas (see below). The neurotropic tendencies of the virus are demonstrable in the monkey by intracerebral inoculation, and simultaneous protection of the viscera by antiserum, to produce an encephalitis. The rabbit and rat are resistant to experimental infection, but encephalitis is produced in the guinea pig on intracerebral inoculation. The infant mouse is susceptible to parenteral inoculation by any route; the adult mouse is susceptible to intracerebral inoculation but is seldom infected by intraperitoneal inoculation. Some strains of mice are considerably more susceptible than others. Passage by intracerebral inoculation in the mouse results in adaptation to the mouse brain, and such strains lose their viscerotropic tendencies and become less virulent for the monkey.

Tissue culture. Neurotropic virus is cultivable without difficulty in the Maitland type of tissue culture of chick embryo which includes nerve tissue, but the unadapted pantropic strains may be difficult to grow. The Asibi strain of yellow fever virus was grown first in mouse embryo tissue culture, then chick embryo tissue culture, and after prolonged passage a variant appeared which

had lost both viscerotropic and neurotropic tendencies. This variant is the 17D strain, now widely used as an immunizing agent.

This strain will form plaques in chick embryo cell monolayers, and the system may be used to titrate antibody. ¹¹¹ It grows in HeLa and KB cell cultures with a cytopathic effect characterized by rounding up of the cells and detachment from the glass. ⁵⁰ It may also be grown in various kinds of primary cell cultures. ⁶⁸ In human embryonic intestine, human amnion or Chang's liver cell culture the virus is demonstrable by the fluorescent antibody technique as a perinuclear fluorescence. ²⁸

Epidemiology. Yellow fever occurs in animal reservoirs of infection and in infected mosquitoes and is transmitted to the vertebrate host by the insect vector. The epidemiological character of the disease is determined by the species and habitat of both vertebrate and invertebrate hosts and occurs in two epidemiological types, the one urban yellow fever, and the other jungle yellow fever.

Urban yellow fever. It was established at the turn of the century that the disease is transmitted to man by Aedes aegypti, and in the urban type of disease the life history of the virus consists of a man-mosquito-man cycle in which the mosquito is infected by man, requires 10 to 15 days at tropical temperatures to become infectious, and remains infected for life. This mosquito is domestic, living largely in and around human habitation, the foci of infection are in urban areas, and the disease is one of communities. Since man-to-man infection does not occur under natural conditions,

control of the vector in urban areas allows control of the human disease. Control programs directed toward this end have been highly successful, and the disease appeared to have been substantially eradicated in the Western Hemisphere by the middle 1920's.

By the late 1920's vellow fever appeared in small communities and rural areas in South America, and it was apparent that the man-mosquito-man cycle may persist in areas in which there are small groups of people in frequent communication with each other. Control consists of extension of mosquito control measures to such small communities and even to rural areas.

Jungle yellow fever. In the early 1930's vellow fever occurred in Brazil in the absence of A. aegypti, and the infection has been found to persist in reservoirs of infection in lower animals and to be transmitted by mosquitoes other than A. aegypti. This is sylvan or jungle yellow fever in which human infection is peripheral to the life history of the virus. The human disease is found in man coming in contact with forests or the edge of forests and tends to occur in adult males whose work takes them to such infected areas. This is in contrast with urban yellow fever in which all ages and both sexes are exposed to equal risk. Infection of man, followed by infection of A. aegypti may, of course, initiate the man-mosquitoman transmission cycle characteristic of urban yellow fever. The endemic foci of jungle yellow fever are in South America, Africa, and Central America, and differ somewhat from one to another of these areas.

South America. The area of endemic infection in South America, as indicated by the occurrence of antibody in young children as well as adults to show the recent or present occurrence of the disease, covers much of the tropical zone, including the Amazon and Orinoco regions, Colombia, the Guianas, and Panama. Within this area forest monkeys appear to be the most important vertebrate host, although in some areas where monkeys are few, marsupials such as the opossum show serological evidence of infection. Some species of monkeys, especially the howler monkey, Alouatta, suffer from epizootics of the disease which are fatal to large numbers of the animals. On the basis of the presence of antibody in the serum of wild caught specimens, the principal genera serving as vertebrate hosts seem to be Alouatta, Cebus, and Ateles, and others may be involved also.

Yellow fever virus has been isolated from forest mosquitoes. Haemagogus capricornii, H. spegazzini, and the subspecies H. spegazzini falco. Other species of the same genus, and one of the genus Trichoprosopon, transmit the disease experimentally and may be regarded as possible vectors. Species of Haemagogus are found over the entire area in South America in which the infection is endemic and are no doubt an important element in the transmission cycle. They "forest-canopy," tree-hole breeding mosquitoes and are found in the tops of trees, rarely coming to the ground except at the edge of the forest.

Africa. 145 In Africa A. aegypti is widely distributed, and both the urban and jungle types of vellow fever occur. As in South America, serological evidence indicates that the vertebrate hosts in the latter form of the disease are forest primates of many species, including lemurs. A. africanus is found in many parts of central Africa and is known to be an important factor in the maintenance of vellow fever virus in the forest of Uganda. Like Haemagogus in South America, it is an arboreal mosquito, and it readily bites monkeys, but does not attack man. A. simpsoni, which bites both monkeys and man, is also present, and is thought to be the mosquito responsible for transmission of the infection from monkeys to man at the edge of the forest.

Central America. 15, 157 The available evidence shows that the jungle type of yellow fever has been moving north. In 1954, after 25 years with no record of yellow fever, cases of the disease occurred in man in Port-of-Spain, Trinidad. Mortality in monkeys was high during that year, and yellow fever virus was isolated from sick monkeys. The virus was also recovered from Haemagogus mosquitoes, and some of the cases of the disease in man were probably acquired from A. aegypti which had not been kept under control, i.e., the urban type of the disease. Similarly, in 1948 cases of yellow fever were reported in eastern Panama for the first time since 1905. It subsequently moved as a wave in a general northwesterly direction into central and western Panama. Costa Rica, and Nicaragua, and reached Honduras in 1954. In early 1956 yellow fever appeared in monkeys in Guatemala, and the virus was isolated from two species of mosquitoes, H. equinis and Sabethes chloropterus. The virus has also been recovered from other Central American mosquitoes, including *H. spegazzini falco*, *H. lucifer*, and an anopheline, but their status as vectors is uncertain.

In contrast to the situation in South America, where Cebus monkeys are in the majority and show little mortality from naturally-acquired yellow fever, the howler (Alouatta) and spider (Ateles) monkeys are predominant in Central America and show a high mortality from yellow fever.

Immunity. Recovery from yellow fever results in a solid immunity, often said to persist for life, and strains of the virus, even from widely separated areas, are of a single antigenic type. The antibody response is demonstrable as HI, complement-fixing, and neutralizing antibodies and the three are not identical. The complement-fixing antibody appears later than neutralizing or HI antibody during infection and may not occur to significant titer in mild infections. It disappears within a few months, and is usually not formed in response to prophylactic inoculation with the 17D strain of virus, and therefore has some value in detecting recent infections. 151

The neutralizing antibody appears quite early in the disease, often by the fifth day, and persists more or less indefinitely. The titration of neutralizing antibody is used for serological surveys for the prevalence of infection. It has been carried out in various ways, and at the present time the method most commonly used consists of mixing varying dilutions of the serum with a stand-

ard amount of virus and testing for residual activity by intracerebral inoculation of adult mice or intraperitoneal inoculation of infant mice.

Prophylaxis. While vector control suffices to control urban yellow fever, it is ineffective in the control of the jungle type of the disease, and in this and certain other circumstances active prophylactic immunization is required. It was early apparent that inactivated virus does not induce an effective immune response,²⁷ and living attenuated virus is used. Two kinds of virus are used for this purpose, one a mouse-adapted neurotropic strain which is used largely by the French in Africa, and the other the 17D strain described above.

The former is employed as a lyophilized preparation which is suspended in a solution of gum arabic just before use and applied by scarification. As used by the French workers in Africa, it is often combined with vaccinia virus. Vaccine is prepared from the 17D strain as lyophilized chick embryo tissue, reconstituted in saline, and inoculated subcutaneously in doses containing 500 mouse MLD. The incidence of untoward reactions is low, perhaps 5 per cent, and such reactions are usually mild. The neurotropic strain appears to give a somewhat better immune response than the 17D strain as measured by neutralizing antibody titer, and in either case the immunity so produced is effective for considerable periods of time; persisting antibody titers have been found in immunized persons as long as 17 to 19 years after primary inoculation. 49, 118

The Tickborne Viruses of Group B

The arboviruses transmitted by various species of ticks are set apart epidemiologically from the mosquito-borne viruses. Some fall into group B as a relatively homogeneous subgroup, the Russian spring-summer encephalitis complex, within which the component viruses are more closely related to one another than to the other members of group B. In addition to those considered here, the tickborne viruses of this subgroup include the Entebbe, Langat, and Negishi viruses. Other tickborne viruses are unrelated to group B. Of these, some fall into two small groups of antigenically related viruses, that made up of the Chenunda. Nyamanini, and Quaranfil viruses and that

including the Kemerovo, Koliba, Lipovnik, and Tribec viruses. The miscellany of sero-logically unrelated viruses includes the Crimean hemorrhagic fever, Kaisodi, Nairobi sheep disease, Silverwater, Thogoto, Wad Medani, and tickborne Witwatersrand viruses.

RUSSIAN SPRING-SUMMER ENCEPHALITIS^{138, 147}

Russian spring-summer encephalitis, or RSSE (Russian Far East encephalitis, Russian forest-spring encephalitis, Russian tickborne encephalitis, Russian vernal en-

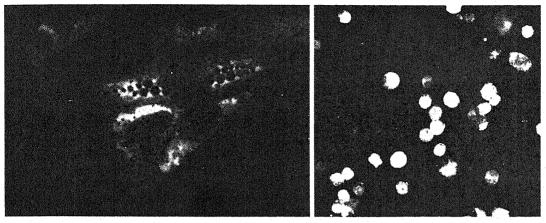

Figure 297. Fluorescent antibody stained tickborne encephalitis virus in chick embryo cell culture. *Left*, smear of cells from culture showing immunofluorescence in some of the cells. × 800. *Right*, fluorescent virus in the cytoplasma of infected cells. × 200. (Albrecht and Kožuch, Bull. Wld. Hlth. Org.)

cephalitis, Russian endemic encephalitis), is not to be confused with Russian autumnal encephalitis, which has been shown to be Japanese B encephalitis. It was observed in 1937 in the far eastern provinces of the Soviet Union and has subsequently been found in other parts of Russia, in Central Europe, including Czechoslovakia, Bulgaria, Poland, Yugoslavia, and Austria, and in Germany.

The virus is 15 to 25 m μ in diameter and may be grown on the allantoic membrane of the embryonated egg and in cultures of human embryo muscle tissue with the production of cytopathology. The mouse may be infected by subcutaneous as well as intracerebral inoculation and is extremely susceptible to mouse-adapted virus. The virus is pathogenic for sheep and rhesus monkeys, but not for guinea pigs or rabbits. A number of wild birds and rodents may be infected experimentally to give a symptomless viremia, and wild rodents have been found to be naturally infected.

The disease in man. The incubation peroid is 10 to 14 days, and the febrile disease in man is characterized by signs and symptoms of a meningoencephalitis or polioencephalitis. It varies in severity from an abortive type of perhaps a week's duration terminating in complete recovery, through a moderately severe, and more prolonged, type of encephalitis with a 20 per cent case fatality rate, and often neurological sequelae in survivors, to a severe fulminating type of meningoencephalitis with death occurring within a week. The overall case fatality rate

is about 30 per cent, but there is a high incidence of antibody in human populations in endemic areas, and it is probable that many infections are symptomless or subclinical.

The gray matter of both brain and cord is involved, with neuronal necrosis and neuronophagia and more marked glial and mesodermal reactions than occur in the other viral encephalitides. The disease is characterized by evidence of bulbar involvement and a peripheral type of flaccid paralysis, most often of the brachial and cervical muscles, which may be residual. In fatal cases parenchymatous degenerative changes may be found in the heart, kidney, and liver. The virus is present in the blood and spinal fluid during the course of the disease and may be isolated from the brain at autopsy.

Immunity. An immune response is evident two to three weeks after onset of the disease as complement-fixing and neutralizing antibodies in the serum. The solid immunity to reinfection is long lasting and associated with the presence of neutralizing serum antibody which reaches peak titer in two to three months. Russian workers have used formalin-inactivated brain and chick embryo vaccines for active immunization and recommend the administration of hyperimmune goat serum on exposure of susceptible persons.

Epidemiology. The first cases of this disease to be reported were seen in persons whose work took them into forested regions, but it is now clear that the distribution of the disease is less restricted, and it has oc-

curred, sometimes in high incidence, in populated areas with greater numbers of infections in children. As noted above, the incidence of serum antibody may be relatively high in endemic areas, and human infection is doubtless more common than the number of clinical cases of the disease would indicate. Whether or not human infection may, under some circumstances, constitute a significant element of the reservoir of infection is open to question. The infection occurs in goats, and these, and possibly other, domestic animals may be a source of human infection. Human infection may occur by the alimentary route,87 and infection, especially in urban areas, from the milk of infected goats undoubtedly contributes both to human disease and to inapparent but immunizing infections. 110 It is generally believed that the significant reservoir of infection is in wild mammals and birds⁵⁹ in which viremia occurs, but the infection is otherwise essentially symptomless.

The infection is transmitted by ticks, of which *Ixodes persulcatus* is regarded as the principal vector. The infection is congenital in these ticks, infection rates as high as 40 per cent have been found in certain small areas, and there is little doubt that there is an arthropod reservoir of infection. Natural infection of other ticks, *Haemaphysalis concinna*, *Dermacentor sylvarum*, and so-called gamasid ticks or mites found in bird and rodent nests, has been found also.

Human infection is acquired in forests from infected ticks which act as both a reservoir of infection and a vector in the maintenance of animal reservoirs of the virus. Infection occurring within populated areas may be transmitted in other ways. Infection by ingestion of goat's milk, as noted above, occurs and familial outbreaks of the disease have been described. It has also been found that oral transmission occurs within pheasant flocks, and this virus apparently has an appreciable potential for infection by ingestion.

LOUPING ILL

Louping ill is an encephalomyelitis of sheep characterized by cerebellar ataxia and necrosis of the Purkinje cells of the cerebellum similar to that observed in Japanese B encephalitis. The term louping (leaping) refers to the peculiar gait of affected animals. The disease occurs in the spring in Scotland and the northern border counties of England. Human infection has been found in Northern Ireland, 89 where it has been confused with poliomyelitis, and in Sweden. 173

The virus is 15 to 22 m μ in diameter and may be grown in chick embryo tissue culture and on the chorioallantoic membrane of the embryonated egg to produce death of the embryo. It produces fatal encephalitis on intracerebral inoculation in mice, and laboratory and field mice (voles) may be infected by peripheral inoculation. Rhesus monkeys, hamsters, and rats may be infected, the last giving a symptomless infection with viremia. Rabbits and guinea pigs are resistant to infection.

Human infections have occurred in laboratory personnel, and in both man and the sheep the disease is diphasic. In the first phase there is viremia, and in man it is accompanied by fever, headache, malaise, gastrointestinal disturbance, and prostration. After clinical improvement there is a recrudescence with fever and signs and symptoms of encephalitis. Recovery has been complete in the human cases which have been observed.

The virus is transmitted by the tick *Ixodes ricinus*. Ticks may be infected by sheep during the viremic stage of the disease, and the infection is congenital in the tick. Whether there are mammalian reservoirs of infection, such as Microtus, is not clear.

Neutralizing and complement-fixing antibodies are produced in response to infection and to immunization with vaccine. There is almost complete cross-protection between this virus and that of RSSE. The two viruses are not identical immunologically and, according to Casals, differences are evident as somewhat higher homologous antibody titers and a significant difference in protection when the challenge inoculum is given peripherally rather than intracerebrally in mice. There would appear also to be differences in the pathogenicity of the two viruses for man.

KYASANUR FOREST DISEASE^{107, 170}

This disease appeared in the Kyasanur Forest in the Shimoga district of Mysore,

Constitution Constitution and American

India, in 1956, and was studied for the first time in 1957. Widespread deaths occurred in native monkeys, the langur monkey (*Presbytis entellus*), and the bonnet monkey (*Macaca radiata*), and there was associated disease in man. During the summer (February-April) of 1957 the disease extended over an area of about 500 square miles, and there were 500 human cases of the disease with 70 deaths.

The disease in man does not simulate encephalitis but rather involves the hematopoietic system. Hemorrhage is the obvious major clinical symptom, with evidence of massive hemorrhage in the chest cavity in fatal cases. The source of infection appears to be monkeys,⁷² and possibly rodents are infected also. The infection is not transmitted by mosquitoes, but there is reason to believe that Haemaphysalis ticks may be the vector.¹⁶¹ An accidental infection occurred in the laboratory in the absence of an insect vector.

A virus was isolated from monkeys and also from the blood in human cases of the disease by Work, Trapido, and their colleagues. 169, 172 The viremic period in man is relatively prolonged, and the blood has been found to be infectious from two days before to as long as 10 days after onset of the disease. The KFD virus is cultivable in chick embryo tissue culture and produces cytopathic effects, and the mouse may be infected by intracerebral inoculation to produce a disease in three or four days characterized by prostration, hind limb paralysis, and tremors. Antibody-fixing complement in the presence of mouse brain antigen and neutralizing antibody demonstrable in the mouse are found in convalescents. The virus appears to be antigenically closely related to, but not identical with, the RSSE virus.

A similar hemorrhagic disease, Omsk hemorrhagic fever, has been described in Russia^{86, 94} as of similar etiology. Observations such as these suggest that the virus of RSSE is a member of a group or complex of closely related viruses, some of which produce encephalitis in man with the characteristic paralysis described above, but louping ill virus infections in man are not predominantly encephalitic, and infections with still other of these viruses are characterized by hemorrhagic symptoms.

POWASSAN VIRUS

Powassan virus was isolated from a fatal case of encephalitis in Ontario in 1958 by intracerebral inoculation of suckling mice. The proved to belong to hemagglutinin group B and closely related to RSSE, the first member of the group to be isolated in the Americas. It is found in various forest mammals and their ticks in Canada, and has also been found in New York state. Apparently the same virus was isolated from pools of Dermacentor andersoni collected in Colorado some years earlier, but not identified until the Powassan isolate was described. 154

COLORADO TICK FEVER

Colorado tick fever (American mountain fever, mountain fever, mountain tick fever, tick fever, nonexanthematous tick fever) occurs in the Rocky Mountain regions of the United States where the tick vector is prevalent. The disease in man was described as a clinical entity in 1930 but probably accounted for some part of febrile disease reported by military personnel in that area in earlier years.

The viral nature of the etiological agent was established by serial transmission of the disease in man and in hamsters by the parenteral inoculation of blood, serum, and filtered preparations in 1944. In 1947 it was adapted to the mouse by intracerebral passage in the suckling animal, and the mouseadapted virus grown in the yolk sac of the embyronated egg, where the virus is found largely in the central nervous system of the embyro. Such embryo-adapted strains are of reduced virulence for man. It has also been grown with CPE in cultures of KB epithelial carcinoma cells109 and in L and FL cells after adaptation to the mouse brain. 159 The virus has been isolated directly from infected human or monkey blood or from ticks by this tissue culture method. There is some discrepancy in the reported size of the virus; according to one report is it is extremely small, 10 m μ , and to another 35 to 50 m μ . Its chemical and physical properties have been described by Trent and Scott. 160

It is set apart serologically from the other tickborne viruses of encephalitides in that it is not a member of group B, nor is it related to the other defined HI groups; it is considered to be an ungrouped arbovirus.

On intracerebral inoculation of mice and hamsters, the virus produces lesions similar to those of louping ill virus, *i.e.*, subcortical vascular engorgement and petechial hemorrhages in the cerebrum and destruction of the Purkinje cells.¹⁰⁴ Cytoplasmic inclusion bodies are found in the Purkinje cells and in the neurones of the hippocampus and pons. The experimental infection in the rhesus monkey, by the intravenous or subcutaneous routes, is essentially asymptomatic, but viremia occurs and persists for four to five weeks.⁴⁴

The disease in man. The disease in man is diphasic and is characterized by a sudden onset with chills and aching, and the symptoms include headache, backache, anorexia, nausea, and muscular pains. With the appearance of symptoms there is a febrile reaction which persists for about two days, and a period of remission occurs, with recrudesence in two or three days. Convalescence may be relatively prolonged but is without complications, and recovery is complete; no deaths from the disease have been reported.

Immunity. Complement-fixing¹⁵² and neutralizing⁴³ antibodies are produced in

response to infection, appearing by two weeks after onset of the disease, and persisting for at least as long as three years. Experimental inoculation of human volunteers has shown that there is a solid immunity to reinfection. Active chick embryo-adapted virus used as an immunizing agent produces a solid immunity, and formalin-inactivated virus purified from mouse brain has also been prepared. 155

Epidemiology. The wood tick, Dermacentor andersoni, is naturally infected with the virus, the infection is congenital, and the tick is a reservoir of infection. 120 The virus has been isolated from the dog tick, D. variabilis, on Long Island, but no human cases of the disease have been recognized there, and D. andersoni is considered to be the primary, and possibly sole, vector of the infection. The virus also occurs in a vertebrate reservoir of infection, in the Colombian ground squirrel, Citellus comunbianus, as indicated by serological evidence, and has been isolated directly from the goldenmantled ground squirrel, Citellus lateralis lateralis, and from the porcupine, Erethizon dorsatum epixanthum. 12, 13, 34 Human infection is acquired from infected ticks and tends to occur in persons exposed to tick bites by occupation, as in adult males.

The Bunyamwera Group of Viruses

The Bunyamwera virus has provided a nucleus for the serological grouping of a number of subsequently discovered viruses to give an informal group known as the Bunyamwera group which contains a few more viruses than the several so-called small groups of arboviruses. The Cache Valley and Wyeomyia viruses are considered here, but the group also includes the Chittoor, Germistan, Guaroa, Ilesha, Kairi, and Sororoca viruses.

BUNYAMWERA VIRUS

DEPOCATIONS FOR STANKING

This virus was isolated in 1943, from Aedes mosquitoes caught in an uninhabited part of the Semliki Forest, by the intracerebral inoculation of mice. 136 It produces a lethal infection in hamsters inoculated by

the intracerebral or subcutaneous routes but not in guinea pigs by the intraperitoneal route. Embryonated eggs may be infected by yolk sac or amnionic cavity inoculation, and the embryo is killed. Gross lesions are confined to occasional hemorrhage in the brain, where the virus is present in higher concentrations than in the body, and the virus is neurotropic in the embryo. It is 70 to 120 m μ . The virus is pathogenic for man as shown by the occurrence of disease, once as an encephalitis, in two of four volunteers inoculated, ¹³⁹ and naturally occurring infection has been observed. ⁸⁰

CACHE VALLEY VIRUS

This virus was isolated from a pool of Culiseta inornanta collected in the Cache

Valley in northern Utah by intracerebral inoculation of weanling mice, 65 and can be grown in hamster kidney cell culture to produce cytopathic effects. There is serological evidence of infection of horses in the area, but not in man. The virus has also been found in Brazil, and was isolated from a pool of *Aedes scapularis* Trinidad. 31 In Trinidad there was serological evidence of infection in horses and monkeys (Alouatta) and in one-third or more of human serums examined.

WYEOMYIA VIRUS

This virus was isolated by Roca-Garcia¹¹⁷ in Colombia in 1940 from *Wyeomyia mela-nocephala* and has been isolated from man, a human case of mild febrile illness, in Panama.¹⁴⁰ It is 70 to 120 m μ in diamter and produces encephalitis in the infant mouse following intracerebral inoculation. It is feebly pathogenic for the chick embryo, growing only when inoculated intracerebrally, and will not grow in other parts of the embryonated egg.

Other Mosquito-borne Viruses

A considerable number of mosquitoborne arboviruses are known which are serologically independent or are immunologically related to only one or two other viruses. Those of sandfly fever, Rift Valley fever, and the Turlock virus stand apart, while the California virus is the nucleus of a small group containing the Lumbo, Melao, Tahyna, and Trivittatus viruses. Others are the Simbu and related viruses, the Bakau and related viruses, and the Koongal, Mossuril, Nyando, and mosquito-borne Witwatersrand viruses.

SANDFLY FEVER^{121, 122}

Sandfly fever (pappataci fever, phlebotomus fever, three-day fever) is an acute nonfatal disease of man of viral etiology which is transmitted by a species of sandfly, Phlebotomus papatasii. 128 Its geographical distribution is limited by the occurrence of the vector, and it is found in tropical and subtropical regions during the hot dry season. These areas include various portions of the Mediterranean littoral and the Middle and Far East. The occurrence of the disease in Austrian military personnel in the Adriatic region led to the basic studies of the Austrian military commision in 1909 which substantiated the role of P. papatasii as a vector, which had been indicated by earlier epidemiological studies, and established the viral nature of the etiological agent.

The virus has been found to be 40 to 60 m μ in diameter and occurs as two serotypes, the Sicilian and Naples types. It does not infect the usual laboratory animals, including

primates, and is not cultivable in the chick embryo or in tissue culture. It has been established in the mouse by intracerebral inoculation of the newborn mouse, producing encephalitis with lesions occurring predominantly in the hypothalamus and midbrain, after three blind passages in the case of the Sicilian type and one blind passage of the Naples type. By the tenth passage in infant mice, the Sicilian virus produced a fatal infection in the adult mouse and was fully adapted by the twenty-fifth passage. The adapted virus did not produce disease in rhesus monkeys, rabbits, guinea pigs, or hamsters but did induce an immune response. It had also lost pathogenicity for man but produced an immunity to the nonadapted virus.

The Naples strain was not regularly pathogenic for weaned mice until the thirty-fifth passage, and by the fifty-fifth passage was fully adapted, i.e., virus was found in equal titer in both newborn and weaned mice. In contrast to the Sicilian type, the mouseadapted Naples type produced a mild disease in rhesus monkeys on intracerebral inoculation, but did not infect other experimental animals. Both serological types are cultivable in human or mouse kidney cell culture after mouse passage. A cytopathic effect and plaque formation occurs in the human cell cultures after three to four tissue culture passages, but on first passage in mouse cells.62

The disease in man. The incubation period of sandfly fever is usually three or four days. There may be prodromal malaise and abdominal distress. In the febrile period the viremia is of a lower level than in

dengue, with perhaps 1000 MID per ml. of virus present in the blood. The symptoms, occurring in various combinations, include nausea, headache, backache, stiffness in the neck and back, pains in the joints, sore throat, and anorexia, but there is no rash as in dengue. The febrile period lasts for two to four days, and during convalescence there may be diarrhea and weakness. Relapse occurs during convalescence in some small portion of cases. The disease is rarely if ever fatal.

Immunity. Two or more attacks of the disease may occur during the same season, and this has led to the belief that an effective immunity is not produced by the infection. Controlled experiments in human volunteers, however, have shown that there is a solid immunity to the homologous virus serotype which persists for a considerable time, but that there is substantially no crossimmunity between serotypes. The development of mouse-adapted strains of both known serotypes has made possible both complement-fixation tests, using mouse brain antigen, and mouse protection tests. and the application of both of these has fully substantiated the antigenic independence of the serotypes. Active immunization of man with mouse-adapted virus has been demonstrated experimentally, and immunization against the disease, and also dengue, may assume some practical importance under certain circumstances, as in military operations.

Epidemiology. There appears to be no vertebrate host other than man, and *P. papatasii* is the only known vector of the infection. There is some evidence which has been taken to suggest that congenital transmission of the infection in the vector may occur, but this has not been established. The seasonal occurrence and short life of the vector, together with the self-limited nature of the infection in man, has been thought to imply some other reservoir of infection, but as yet this remains purely hypothetical.

RIFT VALLEY FEVER¹⁰⁵

Rift Valley fever (enzootic hepatitis) is a disease of viral etiology which was first observed in 1930 in domestic animals and man in the Rift Valley in Kenya, South

Africa. Serological evidence, *i.e.*, mouse-protective antibody, indicates that the infection is widespread in Africa, occurring in Uganda, the Sudan, French Equatorial Africa, and the Union of South Africa, as well as in Kenya.

The virus is 23 to 35 m μ in size and is almost uniquely stable, serum remaining infective for as long as two years at refrigerator temperatures. It is cultivable in chick embryo tissue culture and in the chick embryo and is pathogenic for most experimental animals except the guinea pig, but it does not infect chickens, canaries, or pigeons. Mice are especially susceptible, and the experimental infection is fatal within four days. South American monkeys are somewhat more susceptible than African monkeys and respond with a febrile reaction, while the infection in African monkeys is symptomless although there is viremia. Neurotropic strains of the virus have been produced by intracerebral passage in mice. A variant, described as Lunyo virus, has been isolated from mosquitoes and a monkey in Uganda which, unlike RVF virus, produces an encephalitis in mice associated with intranuclear eosinophilic inclusion bodies.¹⁶⁴ This naturally occurring neurotropic strain could be made viscerotropic by intraperitoneal passage in the mouse.

Natural infection occurs in cattle and sheep, but not horses, with a 10 to 20 per cent mortality in adults and abortion in pregnant ewes. Young lambs are very susceptible to infection, and the mortality rate may be as high as 90 per cent. The characteristic lesion seen at autopsy is focal necrosis in the liver, beginning, like that of yellow fever, in the midzone of a lobule. The degeneration is of a hyaline type, and isolated cells are similar to the Councilman bodies seen in yellow fever. In the fulminating disease in lambs the destruction is very extensive and may involve practically all of the parenchymatous cells.

Naturally occurring disease in man is found in persons associated with infected animals, such as shepherds and veterinarians. The disease seems to be especially infectious for laboratory workers, and there have been a considerable number of such infections. The incubation period is five to six days, and the onset of the disease is abrupt. It resembles dengue, with pain in the extremities and joints that may be extreme. The febrile phase lasts only a few

days, convalescence is rapid, and recovery complete, and the disease is rarely fatal. In both man and lower animals a solid immunity results from the infection, and both complement-fixing and neutralizing antibodies are present in the serum.

The disease is transmitted among animals by blood-sucking arthropods which feed during the night. The mosquito Eretmapodites chrysogaster has been found naturally infected in the Semliki forest in Uganda and shown to transmit the disease under experimental conditions. A. caballus and C. theileri appear to be the natural vectors of the infection in South Africa. 142 Epidemiological observations suggest a wild animal reservoir of infection, but such a reservoir has not been found, and it is not known how the infection is maintained in interepidemic periods. The disease seems not to be transmitted among susceptible animals by contact, and the way in which accidental laboratory infections are acquired is unknown.

CALIFORNIA VIRUS¹¹⁴

Three strains of this virus were isolated in 1943 from pools of A. dorsalis and C. tarsalis by intracerebral inoculation of young mice; they produced encephalitis in these animals, cotton rats, and hamsters. Inapparent infection with viremia was produced in ground squirrels, but calves and chickens were not susceptible. The virus grew well in the chick embryo and in other parts of the embryonated egg, but usually without death of the embryo. It was found to be 60 to 125 m μ in diameter and immunologically distinct from the other arthropodborne viruses. It is unrelated to the main HI groups of arboviruses, but is part of a small serologically distinct group which also contains the Lumbo, Melao, Tahyna, and Trivittatus viruses.

This virus was found only in the San Joaquin Valley in California, and within Kern Country, where it continues to persist in endemic form. 48 There was serological evidence of infection in man, horses, cattle, rabbits, and ground squirrels. This virus was the probable cause of fatal encephalitis in an infant, and the possible cause of disease in two other persons, but has not been

isolated from man or other mammals. It is believed that it occurs as a reservoir of infection in lower animals, and the infection is maintained, and transmitted to man, by mosquitoes to give a symptomless or subclinical infection.

TURLOCK VIRUS84, 165

This virus was isolated from C. tarsalis in California by intracerebral inoculation of infant mice. It grows in the embryonated egg, killing the embryo in two to six days, and may be cultivated in chick embryo cell culture. It was found to be relatively large, 120 to 180 m μ in diameter, and, by the complement-fixation reaction, unrelated to other arthropod-borne viruses except the Umbre virus. It is not known to cause disease in man.

BWAMBA FEVER VIRUS

Bwamba fever is a mild febrile disease of man which occurs in African natives in Uganda. The disease is characterized by abrupt onset with fever, headache, backache, mild conjunctival injection, and rash. The disease persists for only a few days, and convalescence is rapid. Nine strains of the causative virus were isolated from the blood¹³⁷ by intracerebral inoculation of mice, producing hyperemia and edema of the brain with degenerative changes in the pyramidal cells of the cortex. The virus is almost completely avirulent for the mouse by peripheral inoculation. A nonfebrile infection is produced in rhesus monkeys. and guinea pigs and rabbits are not susceptible to infection. The virus is cultivable in the embryonated egg by yolk sac inoculation and is found in highest concentration in the brain and body of the embryo. The embryo is not killed, but evidence of gross hemorrhage is found in the brain. The virus is 70 to 120 mu in diameter and is antigenically distinct. It is antigenically related to Pongola virus but not to the other arboviruses. Neutralizing antibody occurs in the native population in proportions ranging from 13 to 81 per cent of serums examined, suggesting that the infection is widespread.

Interrelationships Among Arboviruses

The arthropod-borne viruses have in common a reservoir of infection in lower animals, a transmission cycle in which the infection is carried by biting arthropods, mosquitoes, or ticks, and a general kind of pathogenesis in which there is viremia in the bird or mammalian host and infection of the viscera or central nervous system. depending upon the relative neurotropism of the virus. As noted earlier, human infection is usually incidental to the natural history of the virus although under certain circumstances, as in Aedes-transmitted vellow fever, man may function as a significant host or even a reservoir of infection. There are also other indications that these viruses are more closely related to one another than to other viruses; for example, all the arthropod-borne viruses which have been tested are inactivated by deoxycholate in 1:1000 dilution, while other neurotropic viruses, including poliovirus, mouse encephalitis viruses, and Coxsackie and encephalomyocarditis viruses (see below) are not. 150

Among these viruses there are groups and subgroups of viruses which resemble one another. As indicated earlier, they fall into two general size ranges, those 15 to 30 m μ in diameter and the larger viruses 70 to 120 m μ in diameter, although there are exceptions such as the Sindbis virus which is intermediate in size. The significance of grouping by size is uncertain, for antigenic relationships, for instance, may occur between the larger and smaller viruses.

Immunological relationships are often of basic significance and are also of practical importance in relation to cross-immunity to infection and to serodiagnosis of disease or serological identification of viruses. These viruses, like many other microorganisms, induce the formation of complement-fixing and neutralizing, or protective, antibodies which may be identical but often are not. In addition, many, but not all, of the arthropod-borne viruses agglutinate goose or neonatal chick red blood cells, and, as in the case of influenza and related viruses, the hemagglutinin is antigenic and stimulates the formation of hemagglutinin-inhibiting antibody. The hemagglutinins and complement-fixing antigens are separable by chromatography, and preliminary studies have indicated that virus strains of groups A and B have two hemagglutinins which are antigenically similar, and two complement-fixing antigens are present in strains of group B, but only one, the virus particle, in group A.⁴⁷

Of the three general kinds of serological reactions which are available for the characterization of these viruses, the hemagglutinin-inhibiting antibody is the least specific in that it gives a high proportion of cross-reactions, neutralizing antibody is highly specific, 112 and complement-fixing antibody is intermediate in specificity.

The application of the hemagglutinationinhibition reaction allows the separation of the arthropod-borne viruses into broad groups²⁶ as noted earlier. Groups A and B, the latter being considerably the larger, were distinguished first. With the isolation of related strains, the previously ungrouped Bunyamwera virus provided the basis for a Bunyamwera group.¹⁹ These groupings are shown in the accompanying table with virus strains illustrating the observed separations. A group C was described, 20 which consists of virus strains isolated in Belem (Brazil). Of the remainder, some fall into minor groups made up of two or three related strains, while others are as vet ungrouped. These groupings are given in detail by Casals.¹⁷ It is probable that this grouping can be simplified somewhat by aggregation of closely related viruses as variants of a designated prototype strain.

Subgroups within the hemagglutinin groups may be distinguished by cross-reactions in the complement-fixation reaction in which the titer of heterologous reactions is commonly less than that of the homologous reaction. For example, West Nile, St. Louis encephalitis, Japanese B encephalitis, and Murray Valley encephalitis viruses are related with respect to complementfixing antigens, and yellow fever virus is related to this group and also to dengue and Uganda S viruses. A Japanese B encephalitis antiserum, having a homologous titer of 1:128, may show a titer practically as high against West Nile antigen and one of 1:32 against yellow fever antigen. Or, yellow fever antiserum having a homologous titer of 1:28 may fix complement in titers as high

Hemagglutinin Groups of Arthropod-borne Viruses

GROUP A	GROU	ЛР В	BUNYAMWERA GROUP
EE viruses	St. Louis E	West Nile	Bunyamwera
Mayaro	Yellow fever	Uganda S	Cache Valley
Semliki	Louping ill	Ilheus	Germiston
Uruma	Russian SSE	Powassan	Guaroa
Chikungunya	Kyasanur Forest	Bussuquara	Ilesha
Sindbis	Zika	Dengue viruses	Kairi
O'nyong-nyong	Japanese B	Wesselsbron	Wyeomyia
Middelburg	Murray Valley	Ntava	Chittoor

as 1:32 in the presence of West Nile or Japanese B encephalitis antigen. Similarly, a dengue antiserum having a homologous titer of 1:128 may fix complement with yellow fever antigen in dilutions of 1:8 to 1:32, in the presence of West Nile antigen in dilutions of 1:16 to 1:64, and in the presence of Japanese B encephalitis antigen in dilutions of 1:16 to 1:64. Similar cross-reactions occur between the western and eastern varieties of equine encephalomyelitis virus.

When the more highly specific neutralizing antibodies give heterologous reactions, it is generally taken to be indicative of an extremely close relationship between the viruses. There is, for instance, a partial cross-neutralization between the western and eastern equine encephalitis viruses, and a similar relationship among the West Nile, Japanese B encephalitis, St. Louis encephalitis, and Murray Valley encephalitis vi-

ruses. In the case of Russian spring-summer encephalitis, louping ill, and Kyasanur Forest viruses, the relationship is very close and the differences among these viruses are considered to be of little more than variant status. Semliki Forest virus, Kumba virus, and Mayaro virus give essentially complete cross-neutralization reactions and are therefore regarded as practically identical, and Chikungunya virus is either identical with or closely related to them. These relationships, together with those evident in the complement-fixation reaction, are indicated as subgroups within the hemagglutinin groups in the accompanying table. Such subgroups may not, however, fall entirely within the hemagglutinin groups; the Chikungunya virus, for instance, although closely related to Semliki Forest virus, also cross-reacts to a minor degree with dengue type 1 virus.

Lymphocytic Choriomeningitis

This disease was first observed in 1934, by Armstrong and Lillie, who isolated the virus in a monkey being used in the study of St. Louis encephalitis. The choroid plexuses and meninges were involved, and there was lymphocytic infiltration, these characteristics giving the disease its name. The following year it was found by Traub¹⁵⁸ to be widespread as an endemic, often symptomless, infection in mice, and in 1936 the virus was isolated, both in this country and in England, from human cases of disease diagnosed as aseptic meningitis.

The virus is not an arbovirus in that, so far as is known, it is not arthropod-borne under natural conditions, although Aedes mosquitoes and Cimex can transmit the disease under experimental conditions and it has been found in ticks and the progeny of infected ticks. It resembles the arboviruses in that it is of the same order of size, 40 to 60 m μ and is ether-sensitive and pH labile. It occurs as a single antigenic type. It has been suggested that it may be an arbovirus modified in such a way that it is not usually transmitted by arthropods. It may be grown in mouse or chick embryo tissue culture⁵ and in the embryonated egg on the chorioallantoic membrane or in the yolk sac. In the egg it does not kill the embryo, and the egg may hatch and the chick survive. Strains of high virulence may grow in chick embryo cell monolayers to give plaques on prolonged, 12-day, incubation.

Pathogenicity. 85, 132 The human disease occurs during the cold months of the year, chiefly in adults 20 to 40 years old. It varies in severity from a mild influenza-like disease, through aseptic meningitis or meningoencephalitis, to a fatal systemic form of the disease. The respiratory type of disease may not progress further, and few such cases are recognized as infections with this virus. Or the respiratory symptoms may be prodromal, and the disease progress with the appearance of central nervous system involvement within a few days, including sudden severe headache, fever, nausea, and drowsiness, or the meningitis may occur without prodromata. In the severe form of the disease, which occurs relatively rarely, the symptoms are referable to the portions of the central nervous system affected. During the febrile stage of the disease the virus is present in the blood, nasopharyngeal secretions, and urine, and in the spinal fluid in the meningeal type of disease. Complications are rare and recovery is usually complete.

In the naturally occurring infection in mice two kinds of disease are observed.66 In the one the disease takes a conventional course with the production of complementfixing antibody, and there is persistence of small amounts of virus in various organs. When infection occurs in utero or soon after birth, the resistance of the animals is high and the infection is symptomless. There is apparently no detectable immune response, but the animals are highly resistant to superinfection, and virus is present in large amounts in blood and tissues. The latter kind of infection is considered by some to represent acquired immune tolerance to the agent (see below). In any case, the infection persists in endemic form, and carrier mice represent a reservoir of the virus.

Immunity. Both complement-fixing and neutralizing antibodies are formed in response to the infection. Both appear relatively late in the disease, complement-fixing antibody reaching diagnostic levels in three to four weeks and disappearing within a few months, and neutralizing antibody reaching diagnostic titer in seven to eight weeks after onset of the disease and persisting

for a period of years. The occurrence of immunological tolerance appears to be a significant factor and has been studied at some length. 162

Experimental infections. A number of experimental animals are susceptible to infection, including mice, guinea pigs, dogs, monkeys, and chimpanzees, but rabbits and birds are resistant. The mouse and guinea pig are the experimental animals of choice. The mouse may be infected by intranasal or intracerebral inoculation88 to produce a fatal infection; tremors and convulsions develop in one to two weeks with death two or three days later. Peripheral inoculation, as in the footpad,67 results in a nonfatal infection unless very large doses of virus are given by the intraperitoneal route. The occurrence of virus in the kidneys168 is consistent with the shedding of virus in the urine. Fatal disease is produced in the guinea pig by intracerebral inoculation and may also occur following peripheral inoculation. In both kinds of animals virus is present in the nasal secretions, urine, and feces, and postmortem findings include areas of lymphocytic infiltration in the central nervous system and in the organs, and there may be hepatitis.

Epidemiology. Mice, dogs, and monkeys have been found to be naturally infected with the virus, and it is probable that human infection is most often contracted from mice. The mouse infection is endemic, with infection transmitted *in utero* or shortly after birth and maintained by healthy carriers.¹⁵⁸

It is not clearly established in what way man contracts the infection from the mouse or other animal. It is generally believed that the portal of entry is usually the respiratory tract and that the infection is acquired by inhalation; laboratory infections have occurred which were probably acquired in this way.

The infection in man is doubtless much more common than the number of clinical cases of the disease suggest. Armstrong found that 11 per cent of 2000 persons examined at random had neutralizing serum antibody, and it is probable that many immunizing infections are symptomless or are assumed to be influenza or related respiratory disease.

DURAND'S DISEASE

This is a febrile disease characterized by headache and upper respiratory, meningeal, and gastrointestinal symptoms which Durand³³ described as occurring in himself and in two human patients who were inoculated for pyrotherapeutic purposes. Later Findlay³⁶ acquired the disease as a consequence of a laboratory infection.

During the febrile stage of the disease, lasting for less than a week, the blood is infective for the guinea pig by intracerebral or other routes of inoculation. The experimental disease is characterized by adenopathy, pneumonitis, and enlargement of the spleen, and the fatality rate is about 10 per cent. Mice, hamsters, dogs, cats, and monkeys are also susceptible to experimental infection. In both man and experimental animals complement-fixing and neutralizing antibodies appear in the serum after about a week. The virus is 40 to 60 m μ in diameter, cultivable in chick embryo tissue culture, and on the chorioallantoic membrane of the embryonated egg, to give an infection which is lethal to the embryo. It is immunologically unrelated to the virus of lymphocytic choriomeningitis.
